Control and exercised animals were litter-mates of comparable weight. Animals exercised in a treadmill usually performed 5,000–6,000 revolutions in a 12-h period. The animals used in experiments 1 and 2 were all from the same litter. Likewise for experiments 5 and 6. The specific activities represent the mean of duplicate assays on the combined right and left leg muscles of single rats except in experiments 1 and 2 where the results from a number of animals, indicated in parentheses, are averaged. Enzymatic assays¹³ carried out for convenience in sampling on extract obtained as follows. 1–2 gm thigh muscle from back legs was homogenized in 5–10 vol. 0.25 M sucrose and centrifuged for 20 min at 20,000g. Supernatant was removed and the residue rehomogenized in 5 vol. sucrose, recentrifuged and the supernatant again removed. The residue was once again washed with 5 vol. sucrose and supernatants combined and made up to volume.

The results in Table 2 indicate that when related to total nitrogen content of the muscle the creatine phosphokinase activity in all cases was greater in stimulated muscles than in the resting controls. The greatest increases were obtained when muscles were allowed to equilibrate for 30–60 min in oxygenated Ringer after dissection, stimulated continuously for 4–5 h and then assayed immediately. If after stimulation the muscle and the appropriate control were kept in Ringer overnight at 2° before assay, the difference between enzymatic levels in the rested and stimulated control, although still significant, was somewhat lower. In this respect it is of interest that in the *in vivo* experiments with the rat the largest increases in creatine phosphokinase activities were obtained when assays were made immediately after the exercise period (Table 1). When the exercised animals were allowed to return to normal activity for some hours after the exercise period before removal of the muscle

and enzymatic assay, the differences in level between control and exercised animals were less. This is another factor which may not have been given sufficient attention by investigators who have been unable to demonstrate increases in enzymatic activity after exercise.

The results obtained with mammalian and insect skeletal muscles *in vivo* and *in vitro* with amphibian tissue clearly indicate that continued contractile activity results in an increase in activity of enzymes of special significance for muscle metabolism. This applies particularly to creatine phosphokinase and also to aldolase, 5'-adenylic deaminase and myokinase, although these systems have been studied in less detail. The increases represent a net increase in enzymatic activity when related either to the wet weight or to the total nitrogen content of the tissue. No significant change in nitrogen content due to the periods of activity used either in the *in vitro* or the *in vivo* investigations could be detected.

The increases in creatine phosphokinase could arise in either from activation of an inactive precursor, as in the case of phosphorylase¹⁶, or could be due to the synthesis of new enzyme stimulated by continued contractile activity. As yet there is no evidence of the existence in normal muscle of creatine phosphokinase as an inactive or less active precursor, but this possibility cannot be excluded. If formation of new enzyme occurred, it would be an example of adaptive enzyme synthesis in response to contractile activity and could be explained as a response to the changed metabolic levels in the cell resulting from the continued contractile activity. Although it is not yet possible to decide between these two explanations, the observations that a number of enzymes respond in the same way and that the enzymatic activity of frog sartorius increased with longer periods of activity would support a mechanism involving synthesis of new protein. Such a mechanism would also be supported by the reports¹⁷ that muscle activity causes a stimulation of

Table 2. EFFECT OF REPEATED CONTRACTION ON THE CREATINE PHOSPHOKINASE ACTIVITY OF THE ISOLATED FROG SARTORIUS MUSCLE

Exp. No.	Duration of stimulation (h)	Creatine phosphokinase activity (mg creatine/mg T.N./min)	
		Resting	Stimulated

LIFE-SHORTENING IN MICE EXPOSED TO RADIATION: EFFECTS OF AGE AND OF HYPOXIA

By DR. PATRICIA J. LINDOP and PROF. J. ROTBLAT, C.B.E.
St. Bartholomew's Hospital Medical College, London

IN an investigation of radiation-induced life-shortening described previously^{1,2}, mice were exposed, while breathing air, to single whole-body doses of high-energy X-rays at the age of 4 weeks. Over the range of doses examined (50 to about 800 rads) it was found that the amount of life-shortening was proportional to the dose of radiation, the reduction in life-span amounting to 5.8 weeks per 100 rads. The X-rays used were of an energy of 15 MeV and the dose-rate was about 500 rads/min.

In subsequent experiments³, in which mice were exposed to radiation at different ages, it was found that the life-shortening effect was markedly dependent on age at exposure. It was also found that exposure of mice which were breathing nitrogen for a short time before and during the irradiation resulted in considerable reduction of the life-shortening effect, the protection factor being apparently dependent on age. These were pilot experiments, with small numbers of animals; but the results appeared to justify a full-scale investigation of the effects of age at irradiation and of hypoxia on life-shortening.

The experiment designed for this purpose was on a large scale; it included five age-groups with six dose-levels in each, and the mice were breathing either air, or nitrogen, or oxygen during the irradiation. The total number of mice involved was more than 10,000. Unfortunately, when the investigation was already well advanced, an epidemic of ectromelia hit the colony, and most of the mice had to be destroyed. Further irradiations were carried out afterwards, but on a much-reduced scale, and the results from only a few dose-groups are available. Since it is unlikely that the full-scale investigation will be repeated in the near future, it seems worth while to publish the results obtained so far.

Variation of life-shortening with age at exposure. The experimental conditions were the same as in the investigation of the 4-week age group^{1,2}. SAS/4 albino mice were used, and they breathed air at atmospheric pressure before and during the irradiation. In the older age-groups four mice were exposed at the same time, each in its own container. For the 1-day- and 1-week-old groups, the whole litter from each mother was put in one container and irradiated together. The young mice were returned to their mother immediately after the exposure. At the age of 3 weeks they were weaned and placed in cages, eight mice per cage, like the older age-groups. There they were kept until death; the age at death was noted and a post-mortem examination carried out for pathological lesions. The analysis of the incidence of diseases found at death will be reported elsewhere. This article is concerned only with the effect of radiation on the life-span.

Owing to the small number of mice, the results from both sexes were pooled. It has been shown previously⁴ that for this strain of mice the difference in life-span between males and females is very small. For each dose-group, the mean age at death, and the standard error of the mean, were calculated.

The results are presented in Table 1, and those for the 1-day-old mice are also shown on curve A of Fig. 1. It is seen that for this age-group the experimental points fall quite well on a straight line. Since the lowest dose in this group was about 400 rads, one cannot exclude the possibility of a deviation from linearity at small doses, but this deviation cannot be large. The same applies to the 1-week-old group. For the 8- and 30-week groups results are available for about 100 and 200 rads as well, and in these cases the linearity is much better established.

Assuming this linearity to hold for all age-groups, we can calculate the life-shortening per unit dose. This is given in Table 2 and expressed in weeks per 100 rads; Table 2 also includes the results obtained previously for the 4-weeks group. It is seen that the life-shortening effect decreases with increasing age at exposure. This has

Fig. 1. Mean age at death of mice exposed at 1 day old. A, While breathing air; B, while breathing nitrogen

Table 1. MEAN AGE AT DEATH OF MICE EXPOSED TO A SINGLE WHOLE-BODY DOSE OF RADIATION AT VARIOUS AGES WHILE BREATHING AIR

1 day		1 week		8 weeks		30 weeks	
Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)
0	103.0 ± 4.5	0	104.5 ± 4.0	0	108.2 ± 2.0	0	103.7 ± 1.8
396	81.6 ± 5.0	202	99.5 ± 6.0	103	99.4 ± 1.9	101	105.6 ± 1.7
500	67.5 ± 6.0	403	77.3 ± 3.5	206	94.7 ± 2.1	203	98.7 ± 1.7
594	58.5 ± 3.0	592	65.3 ± 3.0	412	84.6 ± 1.6	408	94.3 ± 1.6
686	55.5 ± 5.0						
794	50.0 ± 4.0						
882	32.5 ± 3.0						

Table 2. LIFE-SHORTENING OF MICE EXPOSED AT DIFFERENT AGES WHILE BREATHING AIR

Age at irradiation	Life-shortening (weeks per 100 rad)
1 day	7.63 ± 0.64
1 week	7.08 ± 1.14
4 weeks	5.77 ± 0.19
8 weeks	5.55 ± 0.56
30 weeks	2.66 ± 0.83

been observed by others for mice at older ages⁵. It has been suggested⁶ that the percentage life-shortening is proportional to the remaining life expectation, and this agrees, within the experimental error, with the results for the older mice. At very young ages, 1 day and 1 week, this does not appear to be the case, the life-shortening effect being too large.

Effect of hypoxia on life-shortening. Mice of the same age-groups as already mentioned were exposed under hypoxic conditions. The mice were anaesthetized with 20–60 mg/kg 'Nembutal' according to age, to avoid convulsions, and were then put into a container through which a stream of nitrogen at body temperature flowed at the rate of 8 l./min. The mice were kept in this nitrogen atmosphere for periods varying from 50 sec for the 1-day-old group to 30 sec for the 30-week group. These times were found by experiment to be the longest which the mice of a given age-group could tolerate without obvious ill-effects. The immediate mortality rate due to nitrogen was less than 10 per cent. Just before the end of the period of nitrogen breathing the mice were exposed to a beam of 15 MeV electrons at a dose-rate of about 40,000 rad/min (1.6 rads/pulse from the linear accelerator, at a repetition frequency of 400 pulses/sec). Immediately after the exposure oxygen was flushed through the container for about a minute to facilitate the revival of the mice.

Owing to limitation in the animal house space, only two dose-levels, about 425 and 900 rads, were used. For each age-group there was also a control group of mice, which went through the same procedure of nitrogen breathing but without receiving any irradiation. To make possible the comparison with the previous results, at each age-group there was also a group of mice exposed under the same irradiation conditions to about 425 rads while breathing air.

The results obtained are summarized in Table 3. A comparison with Table 1 shows that in each age-group exposure while breathing nitrogen considerably reduced the life-shortening effect. The protection against radiation damage by the absence of oxygen, which has been previously found for acute effects^{3,7}, has thus been confirmed for long-term effects as well. However, there are marked differences in this protective action of hypoxia between the older and younger age-groups.

Table 3. EFFECT OF HYPOXIA ON MEAN AGE AT DEATH

Gas	1 day		1 week		8 weeks		30 weeks	
	Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)	Dose (rads)	Mean age (weeks)
N ₂	0	106.0 ± 3.4	0	109.5 ± 2.5	0	101.4 ± 2.6	0	99.4 ± 3.4
Air	434	83.4 ± 3.2	411	81.3 ± 3.5	405	84.1 ± 2.5	453	91.8 ± 5.0
N ₂	430	96.3 ± 2.8	419	100.5 ± 3.2	405	97.1 ± 2.6	454	96.9 ± 3.4
N ₂	920	58.5 ± 4.0	878	65.4 ± 3.9	845	89.9 ± 2.8	937	95.9 ± 3.2

For the 8- and 30-week groups, the life-shortening, although much smaller, is still proportional to the dose. The life-shortening per 100 rad is 1.3 weeks and 0.5 weeks for the two age-groups respectively. A comparison with the life-shortening effect produced by the same age-groups exposed to 425 rads while breathing air shows that breath-

ing nitrogen reduced the effect by about a factor of 3. This is about the maximum which has been found for nitrogen protection in other systems and it shows that the procedure adopted reduced the oxygen tension in the tissues of the mice to very low values.

However, for the two younger age-groups, 1 day and 1 week, exposure under hypoxic conditions appears to have changed the dose response relationship, which is no longer linear. This can be seen for the 1-day-old group on curve B of Fig. 1. It comes out more dramatically when one inspects the survival curves for the mice exposed to different doses at the age of 1 day (Fig. 2). It is seen that the percentage survival of mice exposed to 434 rads while breathing nitrogen differs very little from that of the control mice, thus indicating a large protection effect; whereas the 920-rad group in nitrogen is shifted well to the left.

Because of the curvilinear nature of the life-shortening effect in nitrogen, one cannot quote a specific protection factor for the young mice; all one can say is that the protection is large at small doses, but very small at high doses.

In the absence of a theory of the life-shortening effect, it is not easy to explain the transition from a curvilinear to a linear relation with increasing age. However, several possibilities suggest themselves. For example, one may assume that life-shortening is the result of a number of 'faults' produced in some definite targets, and that such 'faults' may accumulate in the course of time from causes other than radiation. Thus, in the older animal, one hit by a quantum of radiation may be sufficient to produce life-shortening; this would result in a linear relation between the effect and dose. On the other hand, in the young animal, more than one hit is required, hence the curvilinear relation.

Another possibility is to relate life-shortening to specific somatic damage, say to a chromosome break, and to the probability of repair of such damage. It is known that radiation damage may be repaired spontaneously, even if it is in the form of a single chromosome break⁸. If we assume that the probability of such repair is very high in young mice, when irradiated under hypoxic conditions, then little life-shortening would be experienced at exposure to low doses at which only one break is likely to occur. On the other hand, at high doses two breaks may occur; these have a much lower probability of repair, hence the life-shortening would be large. For such a double event the variation of the effect with dose should follow a square law. In fact, in curve B of Fig. 1 the life-shortening is approximately proportional to the square of the dose.

With both hypotheses the effect of age would be more apparent under hypoxic conditions, since in the presence of oxygen the amount of damage by a given quantum of radiation is larger, and one hit may be sufficient even at a young age.

Fig. 2. Survival curves for mice exposed at 1 day old: A, Control; B, 434 rad in nitrogen; C, 430 rad in air; D, 920 rad in nitrogen.

ALTERATION OF HAMSTER CELLS BY NUCLEIC ACID IN VITRO

By KATE SHEPLEY, DR. E. J. AMBROSE and DR. K. S. KIRBY

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London, S.W.3

THERE have been occasional reports in the literature of changes in cell properties brought about by treatment with nucleic acid preparations made from foreign cells. For example, Jones¹ has reported morphological changes brought about by treatment with RNA preparations. Of particular interest are the recent observations of Cohen and Parks² which have demonstrated the transfer of immunological sensitivity to non-immune spleen cells by supplying RNA from immune cells. The RNA was added to a cell suspension of non-immune spleen cells and incubated for 30 min at 37° C. In the experiments described in this article, a few DNA (but mainly RNA) preparations were supplied to the medium of C13 hamster fibroblasts grown in monolayer culture. Stable changes in cell morphology and clonal appearance have been obtained, which persist through subsequent cell generations after removal of the nucleic acid.

Culture of hamster cells. Baby hamster kidney fibroblasts (BHK 21/C13) used in these experiments were between 40 and 50 generations after cloning.

The medium used throughout consisted of 10 per cent calf serum and 10 per cent tryptose phosphate broth (Difco) in Eagle's HeLa medium, as modified by Stoker to contain twice the normal concentration of vitamins and amino-acids. For sub-culture of the cells 0.05 per cent trypsin (Difco) was used in 0.0002 per cent 'Versene' in phosphate buffered saline.

Nucleic acids. RNA and DNA were prepared by one of us (K. S. K.). Nucleic acid was dissolved in sterile Hanks's saline and added to the medium in which the cells were already growing, to give a final concentration of 100 µg/ml. The culture was then allowed to grow for a further 4 days before sub-culture into fresh medium which did not contain nucleic acid. When the cells had been propagated for at least 3 generations, they were trypsinized and planted in Petri dishes in numbers appropriate to colony formation (usually 5×10^3 cells in a 6-cm dish). After 7 days the cultures were fixed in 10 per cent formol saline and stained with a Jenner-Giemsa stain.

Effects of various types of foreign RNA. In the presence of any foreign RNA, cells grew much faster than a control culture. The whole monolayer became thick and tended to strip, and the medium became acid. On sub-culture, the rapid growth-rate was not so noticeable, but if a small number of cells were planted in a Petri dish, a number of the colonies formed in 7 days were large, piled up and deeply staining, compared with the relatively small, flat colonies formed by normal cells (Fig. 1b). In contrast to the piled-up colonies formed by polyoma virus transformed cells, which grow in an irregular criss-cross pattern (Fig. 1a), these colonies retained the regular parallel growth of the normal colonies (Fig. 1c).

RNA isolated from hamster kidney, rat liver, *B. subtilis* and polyoma virus-transformed hamster kidney fibroblasts all produced large colonies, the greatest effect being with the RNA isolated from a stilboestrol-induced kidney tumour of the hamster, where up to 20 per cent of the colonies formed were of the altered morphology. The RNA isolated from the BHK 21/C13 themselves had no effect.

It made no difference to the effect of the RNA whether it was added directly to the Petri dish when the cells were planted for colony growth, or whether several generations were allowed to elapse between treatment and planting as has already been described.

Fig. 1. a, Bottom right: colony of C13 hamster fibroblasts showing parallel alignment of groups of spindle-shaped cells. Centre and top left: colonies of polyoma virus transformed cells showing more random pattern of growth. b, Petri dish showing plating out in a new medium in the absence of RNA of cells previously treated with tumour RNA. Faint and diffuse normal colonies can be seen, also dense colonies of stable variants arising from RNA treatment. c, Higher power view of RNA variant. Reasonably parallel alignment of denser regions. More random pattern of growth in the outer regions.

Fig. 2. Interference microscopy of normal and treated clones

Effect of ribonuclease, nucleosides and nucleic acid bases. If, in place of the RNA, the cells were incubated with a mixture of ribonucleosides, or a mixture of adenine,

guanine, cytosine and uracil, no large colonies formed. However, if any of the foreign RNAs mentioned were pre-treated with ribonuclease and the cells incubated as usual with the product of digestion, the same large colonies formed as with whole RNA. This indicated that the oligonucleotide core of the RNA molecule is the part which effects the alteration of the cells.

Interference measurements. By means of an interference microscope, the difference in optical path between a cell and air at a space on the glass near the cell has been measured and the difference taken as a measure of the dry mass per unit area. In this way, a comparison has been made between the dry mass per unit area of cells in an RNA colony and a normal colony. Fig. 2 shows that the average reading of cells in an RNA colony is greater than that of a normal colony. The large scatter of readings within a group is presumably due to the cells being of a different age after division.

Comparison of normal and RNA cells. Normal BHK 21/C13 cells occasionally do form large piled-up colonies. However, the difference between these and the ones produced by treatment with RNA can be seen by examina-

Fig. 3. *a*, Secondary RNA colony showing absence of spindle-shaped cells. *b*, High power of C13 fibroblasts showing high proportion of spindle-shaped cells. *c*, High power of secondary RNA colony showing characteristic appearance of the cells with numerous independent pseudopodia and absence of spindle-shaped cells at low cell density

tion of the cells at higher magnification. Although the cells in the centre of each colony are thin and spindle-shaped, those on the edge of the RNA colony are large, spread out, often multi-polar, and have large nuclei (Fig. 3c). Presumably those in the centre have been squashed thin by the rapid growth and pressure of adjacent cells. On the edge of the normal colony the cells are as thin and spindle-shaped as in the centre (Figs. 1a and b). When one of the RNA colonies was isolated and grown further, the culture consisted entirely of the large spread-out cells, and this characteristic was retained in the colonies which were grown from single cells (see Fig. 3a). The large piled-up colonies did not form again.

Cultures of these cells have undergone five sub-cultures (approximately 15 generations) since isolation of the original large colony, and the cells still retain these characteristics. Attempts have been made to re-alter the RNA cells back to their original fibroblastic shape by treatment with normal C13 RNA, but without success.

From earlier investigations of cell movements and cell contacts we have good grounds for believing that the appearance of cell colonies in monolayer culture is determined almost entirely by three factors: (1) the polarity of the cell, that is, its tendency to produce one dominant pseudopodium, several independent pseudopodia or numerous microvillae; (2) adhesiveness of the cell to the solid substrate; (3) intercellular adhesions. The polarity appears to depend on local structural or temporal changes in the properties of the cell membrane. The adhesiveness to the solid substrate depends on comparatively non-specific adhesive properties of the cell surface. The intercellular adhesiveness may be partly specific and partly non-specific. Changes in clonal morphology therefore reflect some change which has arisen in the properties of the cell surface.

It may be inferred, therefore, that the alterations after treatment with RNA preparations described in this

chapter have almost certainly produced an altered property of the cell surface, which is transmitted through subsequent cell generations after removal of RNA from the medium. This would suggest that the synthetic mechanism of the cell is disturbed, leading to the production of altered surface material. It is interesting to note that rather similar changes can be brought about by RNA preparations from several sources, though with most frequency by tumour RNA. They are not produced by RNA from the same cell type as the recipients. It is not claimed that the changes described in this article are malignant transformations. When close packed at high sensitivity they show parallel alignment of cells and contact inhibition rather similar to the C13 cells. At low cell density, however, the multiple pseudopodia, more characteristic of malignant cells in culture, appear reproducibly in serial transfer. Qualitatively, the changes in behaviour are rather like those seen in cells transformed with polyoma virus or Rous sarcoma virus, but to a less marked degree. There are several similarities to the malignant change, that is, a number of different agents, viral or chemical, giving rise to a similar end effect in biological terms. The production of a great variety of abnormal surface proteins or mucoproteins may disturb the normal specific interactions which occur in normal tissues and hence may give rise to malignant properties.

We thank Prof. A. Haddow for his advice and Prof. M. Stoker for supplies of C13 and TCY cells. DETERMINATION OF THE TOTAL ALPHA ACTIVITY OF DRINKING WATER USING A NUCLEAR EMULSION

By M. W. TYRRELL, I. C. DEMETSOPOULLOS and A. J. L. COLLINSON

Borough Polytechnic, London, S.E.1

A METHOD is described for estimating the total α -activity of solutions, using 50 μ 'Ilford G5' nuclear emulsions. A tentative value of approximately 10^{-13} c.i.-¹, with a statistical accuracy of 15 per cent, was obtained for the α -activity of a sample of drinking-water from the London area.

Several authors have investigated the use of nuclear emulsions for detecting low-level activities of α emitters in solution. The main methods described are:

(a) Total immersion of the emulsion in the liquid concerned¹; (b) the capillary tube method². This involves the use of thin-wall capillary tubes filled with the liquid sample and placed in contact with the emulsion; (c) mixing the active solution with gelatine and coating the emulsion with the mixture³; (d) sandwiching a drop of the active solution between two emulsions⁴.

All the foregoing methods had a sensitivity below 10^{-10} c.i.-¹. Values for the activity of drinking-water obtained by Turner⁵ indicated that a method was required with a sensitivity in excess of these methods. The technique adopted for this investigation was that of concentrating the activity of the solution, a sample of which was subsequently absorbed in a 50- μ thick emulsion, and counting the number of tracks after suitable exposure and development.

It was assumed that the measured α -activity of the drinking-water was due mainly to radium and its decay products. The daughter element radon (half-life 3.82

days) is a gas at N.T.P. with a freezing-point of -71° C. A subsidiary experiment with a 'clean' emulsion in contact with an emulsion containing absorbed active solution, established that a significant fraction of radon was lost through diffusion. As a consequence of this, it was decided to trap the radon by lowering the temperature to -82° C during exposure, by means of a freezing mixture of solid carbon dioxide and acetone. Dissolved radon was expelled by boiling the solution for 1 h before depositing the sample on the emulsion, thus eliminating the uncertainty as to the initial amount of dissolved radon, the concentration of which could be as high as 1,000 times⁶ the equilibrium value.

The pH of the solution was adjusted to pH 7 to avoid eradication of tracks caused by weakly acidic solutions as found by Ackermann and Faissner⁷.

A small volume of the boiled solution was spread uniformly over a 2 in. \times 2 in. emulsion, the mass deposited being measured by weighing using a sensitive chemical balance. The emulsion was then placed under a bell jar and dried as quickly as possible employing a desiccant and a reduced pressure of 25 torr. The dried emulsion was then transferred to a container kept at -82° C and left for approximately four days before removing and developing using 1D19 developer.

Difficulties were encountered with cracking and peeling of the emulsion after removal from the container. It was found that this effect could be avoided by carefully con-

trolling the rise of temperature of the emulsion. This is contrary to the experience of M. Debearais-Wack⁴, who found that, in order to preserve the emulsion intact, the glass substrate had to be replaced by a cellulose nitrate base.

The emulsions were scanned, using a Cook M40503 nuclear emulsion microscope, by making parallel traverses using a $\times 10$ objective, equipped with a graticule. Each traverse was scanned once, using the fine focus control to include the total thickness of the emulsion, the number of α -tracks being recorded.

With activities in the order of $\mu\mu$ c.l.⁻¹ it was essential to use emulsions not older than three days at the time of exposure. Emulsions older than this were associated with a background which was too high to permit statistically significant measurements without unduly long exposure times. Plastics were chosen for the construction of the emulsion supports since they have a low α contamination, as reported by Yagoda⁵. In order to determine the background a second identical emulsion, but without the active deposit, was introduced into the low-temperature container and both emulsions developed together after exposure.

The activity equivalent background was 0.6×10^{-13} c.l.⁻¹. A solution containing 1.6×10^{-13} g radium l.⁻¹ was used as a standard. Volumes of solution ranging from 0.25 to 1.5 c.c. were deposited on emulsions and exposed. Assuming that only radium was present the number of α -particles emitted for various exposure times from 1 c.c. of standard solution was calculated⁶. The results are plotted in Fig. 1. From the curve it can be seen that for exposure times in excess of 70 h, the increase in the number of α -particles emitted is linear. Since all the exposure times were greater than 70 h, a linear standardization of the results was carried out to find the number of α -particles emitted from the various amounts of standard solution for a set exposure time. The results are plotted against the calculated number of α -particles emitted in Fig. 2.

Comparison of activities of drinking-water obtained by Turner⁵ with that of the standard solution indicated that the standard solution was approximately 400 times more active. Bearing these figures in mind, the drinking water sample was concentrated by a factor of 400 by boiling. This allowed approximately equal exposure times to be used for both the water sample and the standard solution.

Fig. 1. Theoretical activity versus exposure time

Fig. 2. Observed activity versus calculated activity. — · —, calculated; —, measured

It was found that boiling the sample produced a precipitate. This with the solution was deposited on the emulsion. An attempt was made to measure the activity of this precipitate separately and it was found that the activity was not measurable above background.

An analysis of the plate was carried out and the total number of α -particle tracks observed normalized to an exposure time equal to that of the standard solutions. From Fig. 2 the corrected number of α -particles emitted from the sample was extrapolated and found to equal $0.17 \pm 0.02 \mu\mu$ c.l.⁻¹.

In applying statistics to the events, two assumptions were made: the active solution was distributed uniformly over the emulsion surface, and the nuclear events were random. Measurements made indicated the first assumption to be correct. The second assumption is an inherent characteristic of nuclear decay.

Let the plate plus a source be termed A and the plate used for background determination be B . If for plate A the number of traverses was η_A and the number of tracks was N_A and, for plate B , they were η_B and N_B respectively, then the relative standard deviation of the number of disintegrations from the source per traverse equals:

$$\frac{\Delta S}{S} = \frac{\left(\frac{N_A}{\eta_A} + \frac{N_B}{\eta_B}\right)^{\frac{1}{2}}}{N_A - N_B}$$

where S is the number of disintegrations from the source per traverse.

In a paper by Y. K. Lim¹⁰, a method to determine the efficiency in area scanning is described. Although detailed measurements as suggested in the paper were not made, sections of the various emulsions were rescanned. The number of tracks observed in a traverse were found to vary up to 6 per cent on recounting.

It was found that the efficiency depended on several factors. The state of the emulsion in terms of surface scratches was very important: in certain cases, small areas of the emulsion had to be left unscanned as the efficiency dropped enormously. Decrease in efficiency was also observed with increase in time of continuous scanning. Barkas¹¹ discusses most of these points. Less sensitive emulsions, namely $K6$, $K1$ and $K2$ plates, were used in an attempt to reduce the general background, but it was

found that at -82°C the α tracks became tenuous and were difficult to count.

We thank Dr. A. K. M. M. Haque for his assistance, and the Rutherford Laboratory of the Science Research Council for allowing one of us (M. W. T.) time to complete this work.

RELATIVE INSTABILITY OF CEPHALORIDINE TO STAPHYLOCOCCAL PENICILLINASE

By DR. MARK RIDLEY and DR. IAN PHILLIPS

Department of Clinical Microbiology, St. Thomas's Hospital, London

CEPHALORIDINE¹ 7-[(2-thienyl)acetamido]-3-(1-pyridyl-methyl)-3-cephem-4-carboxylic acid betaine) is a semisynthetic antibiotic derived from the nucleus 7-amino-cephalosporanic acid (7-ACA). It shares and combines many of the properties of the semisynthetic penicillins, methicillin, cloxacillin and ampicillin which are derived from the 6-amino-penicillanic acid nucleus (6-APA). Three outstanding properties of cephaloridine are: its relative insusceptibility to staphylococcal penicillinase (β -lactamase), a property which it therefore shares with methicillin and cloxacillin; its broad antibacterial spectrum, which is similar but not identical to that of ampicillin; its lack of cross-allergenicity with antibiotics based on the nucleus 6-APA, which means that it may be given safely to patients hypersensitive to penicillins.

In an attempt to define the place of cephaloridine in current antibiotic therapy a comparison was made of the antistaphylococcal activity of cephaloridine, methicillin and cloxacillin. In preliminary work the minimal inhibitory concentrations of each of these antibiotics for 169 strains of *Staph. aureus*, which had been recently isolated from patients, were determined using large inocula (0.003 ml. of undiluted overnight broth cultures). The minimal inhibitory concentrations were measured by making doubling or closer dilutions of each antibiotic in nutrient agar (Oxoid 'D.S.T.') and recording for each strain the lowest concentration of each antibiotic that caused complete inhibition of visible growth after incubation for

24 and 48 h. The results at 24 h are given in Table 1 and show that with cephaloridine, but not with the other antibiotics, there is a marked gradation of response of different staphylococcal strains. Penicillin-sensitive *Staphylococci* were inhibited by concentrations of cephaloridine ranging from 0.025 $\mu\text{g}/\text{ml.}$ to 0.1 $\mu\text{g}/\text{ml.}$; strains resistant only to penicillin appeared more resistant, requiring 0.25–5 $\mu\text{g}/\text{ml.}$ for inhibition; while multiple antibiotic-resistant *Staphylococci* (resistant to 3 or more antibiotics) were inhibited by 2–20 $\mu\text{g}/\text{ml.}$ Finally, the methicillin-resistant strains shown in Table 1, which were also resistant to multiple antibiotics, were inhibited by concentrations of cephaloridine ranging from 5–50 $\mu\text{g}/\text{ml.}$

It seemed probable that these initial results were due to relative instability of cephaloridine to staphylococcal β -lactamase, compared with methicillin and cloxacillin. The cephaloridine minimal inhibitory concentrations were repeated for each strain on several occasions and revealed that the results were variable for the multiple antibiotic-resistant and to a lesser extent for the strains resistant to penicillin only. Furthermore, the minimal inhibitory concentrations of cephaloridine tended to increase from the figure recorded at 24 h on further incubation to 48 h. No such great variation or increase in minimal inhibitory concentration was observed with methicillin or cloxacillin. The variability was shown to be due to slight differences in inoculum size which cause marked differences in the cephaloridine minimal inhibitory concentrations of penicillinase-

Table 1. MINIMAL INHIBITORY CONCENTRATIONS FOR 169 STRAINS OF *Staph. aureus*

producing strains. Even a small change in inoculum size (six-fold) may cause a marked difference in the minimal inhibitory concentration result, and it is therefore apparent that testing the sensitivity of penicillinase-producing *Staphylococci* to cephaloridine is influenced by inoculum size, a situation which is well known with benzyl penicillin. This effect of inoculum size with cephaloridine has been noted by Barber².

As the effect of inoculum size cannot be taken as *prima facie* evidence for a penicillinase type of resistance³, further experiments to assess this probable penicillinase effect were carried out. A membrane technique described by Knox⁴ as a modification of the Gots⁵ and Haight-Finland⁶ methods was used. In the first series of these experiments large assay plates were poured to contain 300 ml. of nutrient agar in which was incorporated cephaloridine in a final concentration of 1 µg/ml., and 1.5 ml. of an overnight broth culture of a penicillin-sensitive *Staphylococcus* (minimal inhibitory concentration of cephaloridine for this indicator strain was 0.025 µg/ml).

Ninety-one Oxoid membranes were sterilized and placed aseptically on the surface of the medium; each membrane was inoculated, using a wire loop, with a very large inoculum of a single strain of *Staph. aureus* previously grown up on blood agar plates. In this way the 31 *Staph. aureus* strains resistant to penicillin only and the 60 strains resistant to multiple antibiotics were compared simultaneously on the same plate. All these strains appeared to grow well on the membranes, because of the very large inoculum used, although the concentration of cephaloridine (1 µg/ml.) in the plate was close to or even exceeded the minimal inhibitory concentration values previously obtained for some of these same strains. The assay plates were incubated and examined for growth of the indicator *Staphylococcus* after 24 and 48 h. Growth of the indicator strain incorporated in the agar was taken to indicate removal or destruction of the cephaloridine from the medium immediately beneath the membranes. The results of a typical experiment are given in Table 2 (Exp. I).

A modification of these first experiments was introduced in order to avoid any difference between strains due to possible variations in degree of inhibition of growth at the concentration of cephaloridine used. The strains were inoculated on to membranes placed on nutrient agar plates containing no antibiotic. Heavy and approximately equal growth of all strains was obtained after overnight incubation. The membranes were then removed and the agar plugs beneath them were cut out with a cork borer and transferred aseptically to plates containing cephaloridine and the sensitive indicator *Staphylococcus*. The agar plugs were sterile and contained only the diffusible products of the *Staphylococci* which had previously grown on membranes above them. These secondary plates were examined for growth of the indicator bacteria after incubation for 24 and 48 h. Fig. 1 shows this transfer method in use with small standard Petri dishes poured to contain cephaloridine 1 µg/ml. and the indicator strain. It is clear from this experiment that cephaloridine is destroyed by a diffusible product present in the agar and produced by multiple antibiotic resistant *Staphylococci* but not by penicillinase negative *Staphylococci* (including a strain of the Oxford *Staphylococcus* rendered resistant to methicillin *in vitro*), nor in this particular experiment by

Fig. 1. Agar-plug transfer method for detection of drug-destroying enzymes. 1, Penicillin-sensitive *Staph. aureus* strain; 2, penicillin-resistant *Staph. aureus* strain; 3, multiple antibiotic-resistant *Staph. aureus* strain; 4, natural methicillin-resistant *Staph. aureus* strain; 5, Oxford *Staph.* (methicillin-resistant strain); 6, agar plug from beneath uniaeroculated membrane

the penicillin-resistant strain 2, which is a poor penicillinase producer. It seems virtually certain that this diffusible product is a β -lactamase although this has not been formally proved. It is produced in larger amounts by the multiple antibiotic-resistant *Staphylococci*, which tend to produce more penicillinase, as described by Richmond *et al.*⁷, than by the strains resistant to penicillin only. No destruction of methicillin was detected using either the direct membrane or agar plug transfer test. Some slight destruction of cloxacillin was, however, found by the direct technique at 48 h but not at 24 h nor at all by the transfer technique. It is well known that cloxacillin is less stable to staphylococcal penicillinase than methicillin⁸.

Using large assay plates the agar-plug transfer method was compared with the direct membrane method as a means of assessing β -lactamase production by the same ninety-one strains examined in Exp. I. The results of a single experiment are shown in Table 2, Exp. II. The results with the agar plug transfer technique are almost the same as those obtained by the direct membrane technique for the 60 multiple antibiotic-resistant strains, most of which produced a large enough amount of exo-penicillinase in the plugs to destroy the cephaloridine. Different results were, however, obtained with these two techniques for the strains resistant to penicillin only. With the direct technique 10 strains permitted growth of the indicator after 24 h, a further 10 strains after 48 h incubation, and 11 strains appeared to cause no destruction of the antibiotic. It is interesting that these eleven strains included all the phage group II strains in this series of 31 penicillin-resistant *Staphylococci*. Richmond⁹ has shown that of three types of staphylococcal penicillinase,

Table 2. ASSESSMENT OF β -LACTAMASE PRODUCTION BY 91 STRAINS OF *Staph. aureus*

Sensitivity pattern	No. of strains	Exp. I. Membrane			Exp. II. Agar-plug transfer

C	60	57	3	0	51	5	4

Key to sensitivity pattern: B, resistant to penicillin only; C, multiple resistant.

distinguishable on chemical, enzymological and immunological grounds, that with the weakest enzyme activity appears to be produced only by Group II *Staphylococci*. In the transfer technique it will be seen from Table 2 that only five of the penicillin-resistant *Staphylococci* produced destruction of the cephaloridine. These five strains were all among the ten strains that produced growth of the indicator in 24 h in the first experiment. There are several possible reasons for the difference in results obtained by the direct and transfer methods. The transfer method can only measure diffusible (exopenicillinase) and does not therefore take account of cell-bound penicillinase; it also involves an inevitable dilution of the exopenicillinase in the agar plug before transfer; however, the transfer method has the advantage that it avoids any induction of penicillinase in the *Staphylococci*, which do not come into contact with the antibiotic.

In conclusion, it seems clear that cephaloridine is destroyed by staphylococcal penicillinase in circumstances in which no significant destruction of methicillin or cloxacillin could be detected. Three points of interest arise from this finding. First, its possible importance in the treatment of infections due to penicillinase-producing

Staphylococci needs further investigation. Secondly, it makes difficult the assessment of the sensitivity to cephaloridine of penicillinase-producing *Staphylococci*. Thirdly, cephaloridine is a useful tool for simple microbiological assessment of penicillinase production by bacteria because it is more resistant to staphylococcal penicillinase than benzyl penicillin, which is too easily destroyed by all penicillinase-producing *Staphylococci*, but it is less resistant than methicillin, which is scarcely inactivated at all by the staphylococcal enzyme. It may also prove useful in investigations of the inducing capability of penicillins and cephalosporins on different strains of *Staphylococci*.

MEASUREMENTS OF SPONTANEOUS BIOLUMINESCENCE IN THE SEA

By DR. BRIAN P. BODEN, DR. ELIZABETH M. KAMPA and JAMES M. SNODGRASS

Scripps Institution of Oceanography, University of California, San Diego

IN the literature there are numerous reports of strata in the ocean in which the intensity of the ambient light is too high to be accounted for simply by the transmission of sun- and sky-light¹⁻³. Superimposed on this apparently high background level are flashes of considerable magnitude. These strata are generally detected initially by acoustic means, such as sonar, and form the sonic-scattering layers or 'deep-scattering layers'.

Collections made in these layers have revealed concentrations of planktonic organisms associated with concentrations of larger organisms. Many representatives of both the plankton and nekton in such layers are known to be capable of brilliant bioluminescence, and the hypothesis has been that the sometimes rather dramatic increases of light with depth have been due to such bioluminescence. The animals in many of these layers migrate toward and from the surface at dusk and dawn, and experiments made at sea have indicated an increase in flashing rate and intensity at scattering layer levels during such migrations². There has been some implication that this increase may be due to an increased metabolic rate and that it is possibly a means of keeping members of a rapidly moving community in sight of each other.

In common with other workers (for example, ref. 4) we have been uneasy for some time that such apparent increases of light with depth may be artefacts created by agitation caused by the passage of the sensor through the water.

Such reservations about our previous results have led us to design experiments to provide further insight into the question of *in situ* spontaneous bioluminescence, and some very preliminary results are reported here.

Several procedures are open to an investigator of this problem, and they are all unsatisfactory in some respects. Numerous laboratory experiments have demonstrated unequivocally that there is an inherent diurnal luminescent activity in unicellular planktonic organisms such as the dinoflagellates⁵⁻⁷. In most of the experiments, reliance is placed at some time on artificial stimulation—mechanical agitation, light flashes or chemicals. Morris⁴ used a constant-speed propeller to agitate concentrations of

dinoflagellates. Presumably, this could be adapted to undersea observations; but the objection always arises that an artificial stimulus is being applied. This is always true of laboratory investigations.

The same objection can be raised against direct visual observation, either by self-contained under-water breathing apparatus (which has resulted in several tragic deaths) or from submersible craft such as the mesoscapha. Such techniques result in an undesirable perturbation in the natural environment, for a large foreign body, generally equipped with lights, is intruding on it.

We have chosen to take an instrumental approach in which we employ small, dual radiance meters with a coincident circuitry and a common, remote purview. By this means we hope to observe animals in an undisturbed state, for only flashes in a common, approximately spherical field, some distance from the instrument, would be considered spontaneous. Some objections to this system will be discussed later.

The radiance meters. A detailed description of the radiance meters will be published after more definitive experiments have been undertaken. However, a brief description is necessary here.

Each meter is self-contained. The sensor (a model 6472 multiplier phototube similar, electrically, to a model 931-A), power-pack, amplifier circuit, and recorder are contained in one package. The recorder is a 'Minifon' (type L) wire-recorder with a recording time of 4 h.

In the preliminary experiments from which the records described here were obtained the instruments were lowered on single-conductor cable, a sea-return was used, and the signal was monitored and recorded on an Ampex (model No. 403-2) tape-recorder on deck. In routine use, the coincident meters will be lowered on non-electrical, hydrographic or towing cable.

The two undersea units were inter-connected; the signal from the one containing the 'Minifon' was frequency modulated, and that from the other was amplitude modulated. Fig. 1 shows the read-back system.

In front of each phototube was a collimating tube which restricted the incident light to a 10° solid cone. The instruments were mounted on a crude rack and oriented

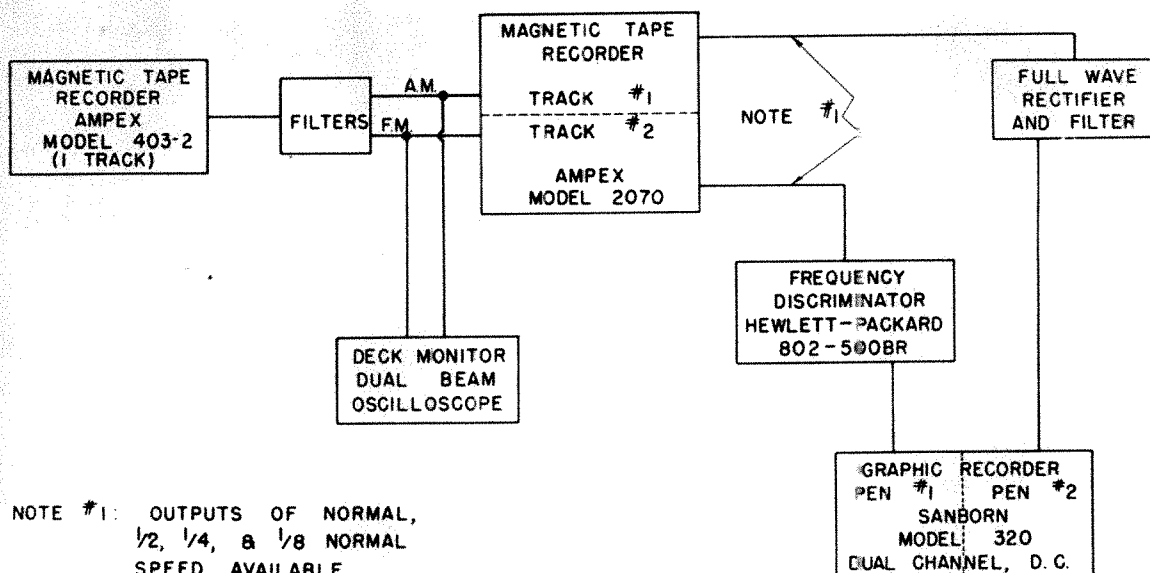

Fig. 1

Fig. 2. Diagram of rack mounting of dual radiance meters, showing 10° cones and region of common purview

so that they observed a common volume of about 1 litre at a distance of 1 metre (Fig. 2). In future use, narrow-band interference filters will be placed between the collimator and the sensor surface.

The original tape records obtained at sea were re-recorded in the laboratory and graphic records were made on a Speedomax recorder (not in Fig. 1) and a Sanborn (model No. 320) dual-channel recorder.

Magnetic tape and the modern magnetic tape recorders and reproducers together constitute an exceedingly versatile and powerful research tool. It is quite practical to 'play back' tapes either faster or slower than originally recorded. We have used this technique to 'slow-down' the light flashes by a factor of eight, so that they may be observed with increased fidelity by mechanical graphic recorders such as the Sanborn model No. 320.

The records. The records shown here were obtained when the dual radiance meters were looking downward. Fig. 3A depicts recorded luminescence above the scattering layer and Fig. 3B shows the increased activity within the layer. The instruments were relatively stationary during each recording. These records were made on the Sanborn recorder at 10 sec/cm chart speed and show what we think may be nearly natural conditions. We enjoyed a zero sea, zero wind and pitch or roll of the ship was minimal.

As we have stated, we consider that only flashes observed coincidentally by the two meters may be spontaneous. For example, Fig. 4 shows what we have considered as a coincident flash (A,A) as well as a non-coincident flash (B). Conceivably, each could have been caused by the

same organism if, for example, it had collided with the frequency-modulated meter outside the common field of vision and an artificially induced flash (B) had resulted. However, this would demand a swimming speed of about 10 msec. Alternatively, the animal could have moved

Fig. 3. A, luminescent activity recorded at 70 m. The sonic-scattering layer was visible on the precision depth recorded at between 125 and 135 metres; B, luminescent activity recorded at 131 m. The radiance meters were stationary in both A and B. The record is expanded by a factor of 8.

out of the field of vision of one of the instruments and flashed again. This is an improbably short flash interval and the likelihood that flash *B* was caused by another organism is high. Objectively, such non-coincident flashes must be disregarded.

During the experiment at sea the output of the frequency-modulated instrument was recorded simultaneously on a Speedomax recorder and on magnetic tape. The Speedomax record resembles closely a record of the same type as those we have obtained previously with a single instrument^{2,3}. We lowered the apparatus to a depth below that of the scattering layer and raised it through the layer. Significantly, during the lowering little change was noticed in the baseline of ambient light. However, during the hoisting of the apparatus through the scattering layer a considerable increase in background light occurred, and the flashes increased in both amplitude and frequency (Fig. 5A). Such activity decreased after the hoisting. The cusps on the base line of the record at the left of Fig. 4A are typical of the records obtained from all such hoists. It is intriguing to contemplate that these cusps may be indicative of inhomogeneities within the layer that are not evinced by acoustic techniques.

The magnetic tape referred to here, both tracks of which were utilized (one by each of the photometers), was re-recorded on the dual-track Sanborn recorder, and a part of this record is depicted in Fig. 5B.

Coincident flashes, which we hope are spontaneous and not artificially caused except during hoistings, were counted, and Table 1 was constructed from the counts.

Table 1. FREQUENCY OF FLASHING IN THE SCATTERING LAYER OBSERVED WITH THE INSTRUMENT IN MOTION AND AT REST

Flashes/2.5 min	Winch activity	Flashes/2.5 min	Winch activity
1	Still	2	Still

2	Still	4	Still
3	Still	3	Still
7	Still	3	Still
3	Lowering 25 m	4	Still
6	Still	0	Still
1	Still	4	Still

Discussion. The foregoing results reveal an apparent increase in bioluminescent activity at scattering-layer depths. They show also, however, that our previous claims, possibly in common with those of other workers, of the magnitude of the increase in activity may have been exaggerated.

Any instrument, subject to surge or being dragged through the water, must cause a physical agitation of the organisms and a possible resultant increase in luminescence which would be recorded uncritically. A serious objection to records we have made previously by means of our irradiance meter is that it is possible for a single organism, such as *Pyrosoma*, to become entangled in the rigging and cause a spurious record. Dual photometers,

Fig. 4. Time-expanded view of a coincident (A-A) and non-coincident (B) flash. The record is expanded by a factor of 8. Only coincident flashes are considered as spontaneous.

Fig. 5. A, luminescence recorded on the Speedomax during a hoisting of the recorders through the scattering layer. The apparatus was hoisted abruptly through about 30 m and then held stationary. It appears that luminescent activity lessens after a period of adjustment; B, a portion of the same record as shown on the Sanborn at an expanded chart speed.

mounted on a single rack and subject to the same forces do of course cause similar agitation. However, since only flashes mutually observed in a distant, undisturbed volume are considered it is probable that the observations system has been purified.

Cogent arguments can be raised that we are not, in fact, actually observing completely spontaneous luminescence in an undisturbed environment.

One of the most plausible arguments would be that the apparatus is causing flashing by agitation and that such flashing is causing sympathetic flashing by other organisms⁶. The design of the instrument precludes its observation of the primary flashes. However, it may conceivably observe flash-induced flashes.

In our opinion these results invalidate the statistics scrutiny to which previous records have been subjected.

These are extremely tentative results obtained on a cruise taken merely to test the instruments.

It is planned that more definite experiments be made soon, and the problem of the amount of sympathetic flashing that occurs in Nature is obviously one of many that will exercise us considerably.

This investigation was supported by U.S. Public Health Service Research grant NB 02841, from the National Institute of Neurological Diseases and Blindness. It was also undertaken under contract between the U.S. Office of Naval Research and the University of California.

PHYSICS

Laser-induced Damage in Diamond

AN observation of laser-induced damage in clear diamond has recently been reported¹ and the conclusions were drawn are that damage occurred on the exit face only and that small holes cannot be drilled because of damage by acoustic phonons. This is contrary to our experience. Using a ruby laser operating in relaxation oscillations with an output of only 0.2 joule and a beam divergence of 3 milliradians, we can produce a hole with 10 laser shots. Fig. 1 shows such a hole of 40 μ diameter through a diamond plate 0.5 mm thick cut parallel to the (10) plane. The laser beam was focused on to the front (10) surface by a plano-convex lens of 17 mm focal length, creating a triangular depression in this surface. Blackening of the walls of the hole also occurred, probably due to graphitization. This diamond plate had also been hit by the same laser operating with a rotating prism Q-switch to give a 5 MW pulse, beam divergence 1 milliradian, focused by an 8-mm microscope objective. Under these conditions blackening and damage occurred on the exit surface only and can be seen on the right of Fig. 1. The microscope objective was wrecked in the process.

Fig. 1. Reflexion two-beam interferogram of diamond plate exit surface showing relaxation-oscillation laser hole on left and giant-pulse laser exit damage on right

Fig. 2 shows an interferogram of another diamond plate which was shattered into two pieces by a single relaxation oscillation beam of 0.2 joule energy. This was a colourless, water-clear diamond plate cut parallel to the (110) plane to form a flat rhombus 3 mm long and 1 mm thick. The surfaces were polished to a fine finish and before laser irradiation the plate was examined with a polarizing microscope which showed it to be free from flaws or serious strain. Focusing was again made on to the front surface with a 17 mm focal length plano-convex lens.

Blackened depressions were observed on both the rear and front surfaces. The front surface depression is 120 μ deep and the exit depression is 30 μ deep, and there was also created a narrow blackened channel going through the crystal along the direction of the beam, and connecting the two depressions. The rest of the diamond plate remained undamaged and colourless. The specimen was cleaved by the laser beam along the (111) plane and the two cleaved surfaces were flat enough to be examined by two-beam interferometry. Fig. 2 shows the two cleaved surfaces set in a matched position with the rear surfaces together. The two cleaved surfaces did not match

exactly; clearly small fragments must have been lost, but in general good matching agreement can be seen in the cleavage features. The fringe patterns are not identical in appearance because fringe direction and dispersion are accidentally determined by the arbitrary inclination between object surface and the optical flat on which it rests.

Four different types of damage have been noted.

(1) Irregular conchoidal fractures along the blackened channel beginning at the bottom of the front surface depression and ending at the bottom of the rear surface depression.

(2) Fine cleavage lines and steps in a large triangular cross-sectioned damage region surrounding the front surface depression.

(3) 'River system' cleavage lines and steps radiating from a starting point on the laser beam path 90 μ from the bottom of the smaller rear surface depression. These are the dominating cleavage features of the damage, and interferometry shows the edges of the cleavage steps to be sharp and reasonably straight.

(4) Conchoidal fractures at the exit point of the laser beam.

It is interesting to note that the directions of the cleavage lines or steps in regions 2 and 3 are not concordant with each other. Also after irradiation some polarization strain was observed around the blackened channel. As with the holed diamond the diameter of the damage channel is smallest near the exit and it would be reasonable to attribute the front surface damage to thermal burning and shock and the rear surface conchoidal fractures and

Fig. 2. Reflexion two-beam interferograms of laser cleaved diamond surfaces. Exit depression is at the centre of the figure

the 'river system' features to acoustic phonons travelling in the direction of the laser beam².

We have drilled a similar hole in a silicon carbide crystal with a single 0.2 joule relaxation-oscillation beam. We also find that with glass slides laser-induced damage can be produced on the front or back surfaces depending on the position of focus. This is contrary to a previous report³ of damage occurring only at the exit face.

This work forms part of a general investigation into laser-induced damage in dielectric materials. We are indebted to Prof. S. Tolansky for suggesting the problem and for valuable advice.

Acoustic Velocity Dispersion in some Non-associated Organic Liquids

OPTICAL-SCATTERING techniques depending on the Brillouin effect¹ enable measurements of acoustic velocity to be made at frequencies above the conventional ultrasonic range, namely, above 10^8 c/s.

When a beam of monochromatic light is incident on a transparent liquid, the scattered light contains two displaced (Brillouin) components, $\nu \pm \Delta\nu$, where $\Delta\nu$ is given by:

$$\frac{\Delta\nu}{\nu} = \frac{2nV}{c} \sin \frac{\theta}{2} \quad (1)$$

with V = velocity of the ultra-high-frequency Debye waves responsible for this part of the scattering, ν = frequency of the incident light, n = refractive index of the liquid, c = velocity of light in *vacuo* and θ = angle of scattering.

Measurement of the Brillouin shift $\Delta\nu$ enables the velocity V to be determined²⁻⁴.

In the work described here, a beam of monochromatic light of $\lambda = 6328 \text{ \AA}$ from a helium-neon laser (of line-width 0.047 cm^{-1}) was passed through the dust-free test liquid contained in a quartz cubical cell. The light scattered at 90° from the liquid fell normally on a Fabry-Perot etalon and fringes produced by the etalon were photographed.

The effects of stray reflexions were reduced to a minimum by placing a collimator between the cell and the etalon. Continuous background scattering that appeared in the fringes was reduced by putting a polaroid filter, suitably oriented, between the scattering cell and the etalon.

A front-reflecting mirror with a dielectric coating of reflectivity 0.99 at $\lambda = 6328 \text{ \AA}$ was mounted in a levelling

Fig. 1

Fig. 2

Fig. 3. B, Brillouin component; C, central component

holder and was placed on the remote side of the cell to reflect back the transmitted laser beam. Another front reflecting mirror was placed behind the cell, facing the collimator, as shown in Fig. 1. This technique has greatly reduced the time of exposure. For some of the photographs taken, an exposure of 30 sec was quite adequate (output power of the laser used was about 2 mW).

Fig. 2 is a photograph showing the Brillouin component for one of the liquids investigated (1-4 dioxan). The two displaced components appear as faint fringes located near the brighter undisplaced ('central') component of the incident laser beam (Fig. 3).

The radii of the fringes were determined and the average shift in frequency, $\Delta\nu$, of the Brillouin components was calculated. The velocity of Debye waves (that is, the acoustic velocity) at ultra-high frequency was then obtained from equation (1). The frequency of these waves is equal to the Brillouin shift, $\Delta\nu$.

The results of the measurements are shown in Table 1.

For benzene, velocity dispersion is evident and confirms the observations of Fabelinskii⁵ and Benedek *et al.*⁶ In *m*-xylene and toluene, no velocity dispersion is shown for 90° scattering. Again, no dispersion is given by 1-4 dioxan.

On the other hand, benzoyl chloride shows dispersion of about 5 per cent, which is outside the range of experimental error; this liquid also shows considerable broadening of the Brillouin components.

Further work is proceeding on a range of liquids. It is worth noting that the upper frequency limit of this technique for a given liquid can be determined from the relationship:

$$f = \frac{2nV}{\lambda} \sin \frac{\theta}{2} \quad (2)$$

where f = frequency of acoustic (Debye) waves, and λ = wave-length of incident light. For some polyatomic

Table 1

Liquid	Temperature (°C)	Brillouin shift (cm ⁻¹)	Frequency ($\times 10^9$ c/s)	Velocity V_{CHF} (m/s)	Ultrasonic velocity ² V_{US} (m/s)	Dispersion $\frac{V_{CHF}-V_{US}}{V_{US}}$
Benzene	22.5	0.164	4.92	1,470 \pm 1%	1,313	12%
m-Xylene	24.1	0.149	4.47	1,330 \pm 1%	1,330	—
Toluene	22.7	0.146	4.38	1,310 \pm 1%	1,321	—
1-4 Dioxan	23.8	0.1465	4.40	1,384 \pm 0.5%	1,379	—
Benzoyl chloride	23.7	0.162	4.86	1,400 \pm 2%	1,335	5%
Ethyl bromide	23.8	0.097	2.91	920 \pm 2%	906	2%

liquids, with 90° scattering and $\lambda = 6328 \text{ \AA}$, a frequency as high as 9×10^9 c/s may be reached. Still higher frequencies may be attained by increasing the angle of scattering or by using shorter light wave-lengths.

We thank Dr. R. W. B. Stephens for his advice.

Fall-out in London Rain-water during 1964

DURING 1964, monthly samples of rain-water have been collected on the roof of the Laboratory of the Government Chemist, Cornwall House, Stamford Street, London, S.E.1, and analysed for the presence of various fission products. This programme was a continuation of the rain-water sampling and radiochemical analysis previously performed at Clement's Inn Passage, Strand, London, W.C.2, during September 1961–December 1963 (ref. 1). The new sampling site is approximately 0.6 miles 15° E. of S. away from the old one. Analytical results for samples taken at both sites during November–December 1963 showed a good measurement of agreement¹. This agreement indicated that the continuity of the radiochemical analyses of London rain-water was undisturbed by the change of site.

The method of sampling has not been altered and the radiochemical procedures employed for the determination of the individual radionuclides have already been described². Regular measurements were made during the year of caesium-137, cerium-144, manganese-54, promethium-147, strontium-90, yttrium-91 and zirconium-95 radionuclides. The levels of these radionuclides are plotted in Fig. 1 on a logarithmic scale, the individual activities being corrected to the mid-point of the sampling period. Throughout the year the changes in the levels of the shorter-lived yttrium-91 (half-life 57 days) and zirconium-95 (half-life 65 days) followed each other closely, as do those of the long-lived nuclides.

Strontium-89 due to the American and Russian tests of 1962 was last positively identified in April 1964 when the level was 0.8 pc./l. Also the levels of yttrium-91 and zirconium-95 were approaching the limits of detection towards the end of the year. The peak levels of radioactivity occurred in May when 33 pc./l. and 59 pc./l. of strontium-90 and caesium-137 respectively were recorded. This compares with the corresponding peaks of 33 pc./l. and 64 pc./l. found during the period June–August 1963. Concentrations of the various radionuclides found in the September sample were relatively high due to an abnormally low rainfall. Thereafter, towards the end of the year, there was a rapid drop, the levels of caesium-137 and

strontium-90 during November–December being the lowest in London rain since October 1962.

Fall-out debris from the low-yield Chinese nuclear test on October 16 did not substantially affect the concentrations of radioactivity in London rain-water during the last three months of the year. After the test, separate sampling was immediately commenced for the determination of iodine-131 (half-life 8.05 days). However, the rainfall was light and the samples correspondingly small (less than 500 ml.) in the fortnight following the test. The first positive identification of iodine-131 was made in rain collected between October 21, p.m. and October 22, a.m. This, and succeeding similarly small samples collected until the end of the month, contained concentrations of 10–60 pc./l. of iodine-131. A modified¹ Glendenin and Metcalf³ procedure was used to isolate the radio-iodine and all counting was performed in low-background anti-coincidence β -counting assemblies.

The other short-lived radionuclides from the Chinese test detected once more in October–December rain samples were barium-140 (half-life 12.8 days) and strontium-89 (half-life 51 days). The results are listed in Table 1. Although they might be expected in fresh fission debris on account of their short half-lives and relatively high fission yields neither cerium-141 (half-life 33.1 days) nor other rare earth activity such as praseodymium-143 (half-life 13.8 days) and neodymium (half-life 11.6 days) were found. The failure to detect cerium-141 was probably due to the inability of absorber measurement to distinguish the β -emission of a small amount of cerium-141 from that of a large preponderance of cerium-144 in a cerium source. Also, the relatively large amount of

Fig. 1. Radionuclides in London rain

Table 1. CONCENTRATION OF SHORT-LIVED RADIONUCLIDES IN LONDON RAIN, OCTOBER TO DECEMBER, 1964

Nuclide	October*	November†	December†
Sr-89	14	6.5	1.10
Ba-140	168	15.5	0.85

* Corrected for decay to the time of the nuclear test (Oct. 16, 1964) and calculated on the rainfall between October 21 and 31, 1964, inclusive.
† Corrected for decay to the mid-point of sampling.

promethium-147 in the rare earth source would mask any small amount of praseodymium-143 and neodymium-147 present.

The successive decreases in the concentration of barium-140 and strontium-89 in Table 1 are larger than would be expected by decay and can be accounted for by dilution of the initial radioactive cloud by dispersal in the troposphere.

Fig. 1 shows that the concentrations of zirconium-95 and yttrium-91 were enhanced during the period of the Chinese test while any small increases in the concentration of the long-lived nuclides were unnoticed graphically.

GEOCHEMISTRY

Strontium-90 and Caesium-137 in Columbia River Plume, July 1964

OCEANOGRAPHERS informally term the extension of Columbia River outflow into the Pacific Ocean as the 'Columbia River plume'. The plume can be identified by its low salinity even at a distance of several hundred kilometres from the mouth of the river (Fig. 1). The plume distributes dissolved and suspended substances in the river water over a wide surface area of the ocean and introduces annually to the euphotic zone over a billion moles of phosphorus and nitrogen fertilizers, as phosphate and nitrate. Equally significantly, the radionuclides contained in the river water are diffused over a wide region¹.

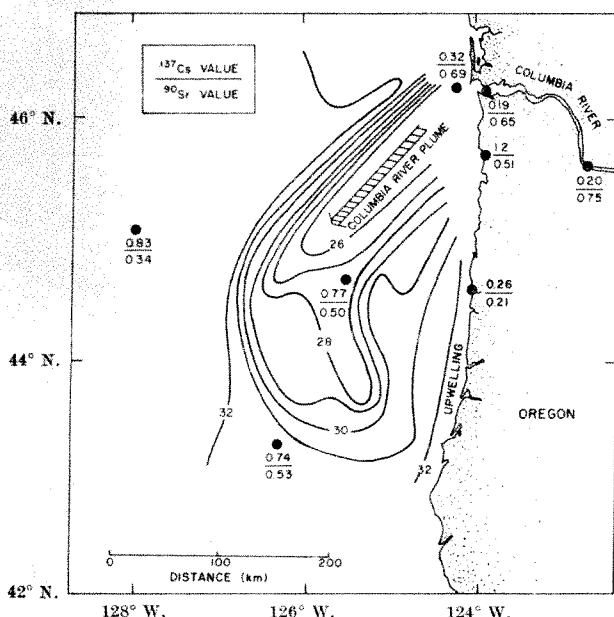

Fig. 1. Surface salinity, ⁹⁰Sr and ¹³⁷Cs distributions in the Columbia River plume, July 1964. Contours are surface salinity in parts per thousand. ⁹⁰Sr and ¹³⁷Cs concentrations are in μCi/l. with a relative standard deviation of ± 10 per cent.

Fig. 2. ⁹⁰Sr and ¹³⁷Cs concentrations in and near the Columbia River plume, July 1964, as a function of salinity

To understand the ocean mixing process of ⁹⁰Sr and ¹³⁷Cs originating in the river, we collected eight 100-l surface-water samples from the river, the river plume, and its vicinity during July 12–24, 1964. The Millipore-filtered water samples were analysed for their ⁹⁰Sr content by the fuming nitric acid method² and for ¹³⁷Cs by the ammonium molybdophosphate method³ at the Meteorological Research Institute, Tokyo. The results and the surface salinity pattern are shown in Fig. 1.

The river water near Portland, Oregon, gave ⁹⁰Sr and ¹³⁷Cs concentrations of 0.75 and 0.20 μCi/l. respectively. The river water contains the radionuclides from two sources: world-wide fall-out and by-product of the operation of the Hanford atomic reactor⁴.

We have no measured concentrations in the river for the isotopes produced at Hanford, but they may be indirectly estimated by comparing the ⁹⁰Sr and ¹³⁷Cs content of Japanese river waters with that of Columbia River water. Japanese waters contain only fall-out. Average Japanese river waters contained 0.19 μCi/l. of ⁹⁰Sr and 0.034 μCi/l. of ¹³⁷Cs in 1961 (ref. 5). At Pasco, downstream from Hanford, the annual average concentration for ⁹⁰Sr in 1962 was 0.7 μCi/l. (ref. 4). If we assume that the ⁹⁰Sr concentrations in Japanese rivers were similar to the fall-out portion of the ⁹⁰Sr content of Columbia River water, then about 0.5 μCi/l. of ⁹⁰Sr would appear to be contributed by the Hanford operation in 1962. Similar ⁹⁰Sr content could have originated from Hanford in 1964.

The sampling station most distant from the shore was more than 300 km off the Oregon coast (Fig. 1). Its water is the least affected by the river plume, and, therefore, should be representative of the oceanic water for this region. We found ⁹⁰Sr and ¹³⁷Cs concentrations of 0.34 and 0.03 μCi/l., respectively, and a salinity of 32.5 parts per thousand. Other waters collected off the coast are in the river plume and can be expected to show effects of a mixture of offshore water and river water. If physical mixing is the only mechanism regulating the concentration of the nuclides, then the plume waters should possess radioisotopic concentrations proportional to the contribution of the two parental water bodies. Fig. 2 confirms this simple mixing theory in first approximation. ⁹⁰Sr appears to have a better linear correlation with salinity than ¹³⁷Cs.

Comparison of the ⁹⁰Sr content in the river water and the offshore water shows that the river water contains about 0.3 μCi/l. more than the offshore water (Fig. 2). Conversely, the ¹³⁷Cs content in the river water is about 0.6 μCi/l. lower than that of the sea water.

A peculiarly high ¹³⁷Cs concentration of 1.2 μCi/l. was observed in the estuarine water of the Nehalem River mouth, about 70 km south of the mouth of the Columbia

River (Fig. 1). No satisfactory explanation is available at present.

The upwelled water at Newport, Oregon, had low ^{87}Sr and ^{137}Cs contents of 0.21 and 0.26 $\mu\text{c./l.}$, respectively. The salinity of this water, 33 parts per thousand, indicates that the water had been upwelled from 100 m depth. The data from the upwelled water appear to confirm the decrease of the nuclide concentration with increasing depth⁶.

Folsom, Mohanrao and Winchell⁷ determined the ^{137}Cs content of sea water along and off the coast of California in 1959 and 1960. Their work is still continuing. According to Folsom (personal communication) ^{137}Cs concentrations off California, between 30° and 35° N., and from the coast to 130° W., were about 0.7 $\mu\text{c./l.}$ in surface waters in 1964. His values are in agreement with ours.

In conclusion we find that both ^{87}Sr and ^{137}Cs concentrations of the Columbia River plume waters are, in first approximation, proportional to the contribution of the river waters as determined from salinity.

We thank Prof. C. L. Osterberg and H. H. Dobson for their assistance. This work was supported by U.S. National Science Foundation grant GP-2232 and by Office of Naval Research contract Nonr 1286(10), project NR 083-102.

Metal Grains in Chondritic Meteorites

THE nickel-iron minerals taenite and kamacite in octahedrites (iron meteorites) are inhomogeneous, as shown in Fig. 1: taenite crystals are richest in nickel and kamacite crystals are poorest in nickel at the phase boundaries where they abut one another¹⁻³. This is a natural consequence of the behaviour of nickel-iron alloy systems if they are cooled slowly and steadily, as in the interior of a planet⁴⁻¹⁰. The binary nickel-iron phase diagram predicts that beneath $\sim 800^\circ\text{C}$, as temperature falls, taenite and kamacite should continuously react with one another and change in composition. Nickel concentration should increase steadily in taenite, while in kamacite at $T < \sim 500^\circ\text{C}$ it should decrease.

A point inside a taenite or kamacite crystal must be able to receive nickel or iron atoms via lattice diffusion from the nearest taenite-kamacite interface (where reaction is occurring) in order to maintain itself at the continuously changing equilibrium composition. But lattice diffusion becomes more and more sluggish with falling temperature, and less able to serve crystal interiors. Interior compositions must eventually lag behind the equilibrium values, leaving centres of taenite crystals poor in nickel, centres of kamacite crystals rich in nickel (at $T < \sim 500^\circ\text{C}$). These are just the inhomogeneities observed in octahedrites.

Chondrites, members of the principal class of stony meteorite, also contain nickel-iron, in minute grains. Urey and Mayeda¹¹ examined these metallographically, and showed that the grains are usually pure kamacite or pure taenite, rarely composite. They noted concentric etch patterns in the taenite grains which indicated that the latter are also inhomogeneous in composition, surrounded by high nickel borders just as is taenite in octahedrites.

Reed¹² analysed metal grains in ten chondrites with an electron microprobe, and found them comparable in composition to kamacite and taenite in octahedrites. He noted that chondritic taenite and most chondritic kamacite are inhomogeneous, but did not define the nature of the inhomogeneities.

More can now be said about chondritic metal grains. An electron-microprobe examination of metal grains in 34 chondrites has been carried out; detailed results will appear elsewhere. Microprobe profiles of nickel content were run over a number of grains in ordinary chondrites. Three representative profiles appear in Fig. 2. Taenite grains were found to be richer in nickel at their surfaces than in their centres, confirming Urey and Mayeda's metallographic observation. Kamacite grains were found to be poorer in nickel at their surfaces than in their centres. In short, taenite and kamacite exhibit exactly the same

Fig. 1. Electron-microprobe profile across Widmanstätten structure in a typical octahedrite (Anoka), showing compositional inhomogeneity of both taenite (t) and kamacite (k) phases.

Fig. 2. Typical microprobe profiles across metal grains in chondrites. Left, taenite grain in Moes; centre, composite grain in Bjurböle; right, kamacite grain in Forest City.

inhomogeneities in chondrites as they do in octahedrites. The only important difference is that in octahedrites, taenite and kamacite are in contact with one another, while in chondrites, they usually occur as discrete grains separated by silicate minerals.

Silicate minerals in ordinary chondrites show textural evidence of thermal recrystallization^{13,14}. The parent chondritic material must have been held at high temperature for a long time. The metal grains could not have survived such an event unchanged: the compositional inhomogeneities we now observe must have been impressed on them as they cooled from this heating. For that to have happened, iron and nickel must have been able to move with great facility from one metal grain to another through intervening silicate material, so that taenite-silicate and kamacite-silicate interfaces in chondrites behaved effectively like taenite-kamacite interfaces in octahedrites.

If taenite crystals in octahedrites have nickel-poor interiors because the effective range of nickel diffusion shortens with lowering temperature, it is obvious that nickel concentration will be lowest at the centre of a crystal, and that the smaller a crystal is or the slower it cooled, the longer diffusion will have been able to supply its centre, and the higher its central nickel content will be. In fact, it is possible, given the dimension of a taenite crystal and its central nickel content, to derive the rate at which it cooled through the temperature range $\sim 600^\circ\text{C} - \sim 400^\circ\text{C}$ in which inhomogeneity developed. (The iron-nickel phase diagram and the coefficient of diffusion of nickel in taenite also must be known, of course.) This has been done for taenite in several octahedrites by programming a digital computer to simulate the diffusion of nickel into slowly cooling taenite crystals^{6,8}.

Since metal grains in chondrites appear to have evolved in a manner quite analogous to that of taenite and kamacite in octahedrites, this method of determining the cooling rate of the system can legitimately be applied to them as well. Theoretical curves relating the central nickel content of a spherical taenite grain to its radius, for several cooling rates (assumed constant), are plotted in Fig. 3.

Fig. 3. Relationship between composition at centres of metal grains and their apparent dimensions, in the chondrite Forest City. Above, taenite; below, kamacite. Curves in upper plot show relationships predicted by theory, for taenite grains in systems that cooled at various rates (given in deg. C per million years)

The method of calculating these appears in ref. 6. Analyses at the centres of taenite grains in the Forest City chondrite are plotted over them. Forest City appears to have cooled through $550^\circ - 450^\circ\text{C}$ at a rate of about 10°C per million years. Similar results were obtained for taenite grains analysed in the ordinary chondrites Moes and Ehle, and in the light portions of the light-dark structured chondrites Pantar and Salles.

It is interesting to note that the analogous diffusion-imposed relationship between size and central nickel content holds for Forest City kamacite grains: the smaller the grain (and hence the shorter the diffusion path), the lower the central nickel content.

The cooling rate obtained allows us to say something about the parent planet or planets in which the ordinary chondrites evolved. Ten degrees per million years is the rate at which the centre of an asteroid some 70 km in radius would have cooled⁶. Alternatively, cooling could have occurred $\sim 70\text{ km}$ beneath the surface of a larger body.

RADIOCHEMISTRY

Site of Attack in the Radiolysis of Pyrimidine Compounds

PREVIOUSLY reported experiments with thymine in dilute aqueous solutions have shown that the site of attack in radiolysis with cobalt-60 γ -rays depends on the pH (ref. 1). In acid and neutral solutions, the principal attack is on the double bond at the carbon atom remote from the methyl group, with ultimate formation of saturated products²⁻⁵. In strongly alkaline solution the attack is largely at the methyl group, with formation of the unsaturated compound, 5-hydroxymethyluracil, as the principal product. The shift in the site of attack as the pH is increased correlates well with a model based on two changes in the reaction path. At least one of these changes appears to be related to ionization of thymine¹.

These findings immediately raise the question of the site of attack in other pyrimidine compounds and in their nucleosides and nucleotides. A set of compounds was therefore selected to permit investigation of this problem relative to the presence of amino, methyl, ribose, deoxyribose, ribose phosphate, and deoxyribose phosphate substituent groups. Strongly acid, neutral, and strongly basic aqueous solutions of each of the compounds, approximately $2 \times 10^{-4}\text{ M}$, were exposed to cobalt-60 γ -radiation. Ultra-violet absorption spectra were measured on a Cary recording spectrophotometer and loss of absorption in

the region 260–280 m μ was determined. The 5,6-double bond of the pyrimidine ring is an essential part of the chromophore group, and a decrease in absorption may be related to saturation of the double bond⁴.

In 0.1 N sulphuric acid solutions, the optical density decreases linearly with radiation dose, and the disappearance yields for the chromophore of uracil, cytosine, and 5-methylcytosine are, within experimental error, the same and equal to 2.9–3.0 molecules per 100 eV absorbed. The yield for thymine⁶ is slightly lower, 2.5–2.7. The presence of a pentose unit on any of the compounds reduces the yields to about 2.4–2.6; the presence of a phosphate on the pentose has little additional effect, lowering the yields only slightly, to 2.3–2.5. Thus radiolytic attack in acid solutions occurs largely at the 5,6-double bond. Neither the 5-methyl group of 5-methylcytosine nor the amino-group of this compound or of cytosine is attacked sufficiently to change the double-bond disappearance yield. The pentose and the pentose-pyrimidine link in the nucleosides and nucleotides are attacked at most to the extent of about 20 per cent of the total reaction, a result in agreement with reference 4.

In alkaline solutions (2 N sodium hydroxide), in contrast, the optical density generally changes non-linearly with radiation dose, and the initial chromophore disappearance yields vary greatly among the different compounds (Table 1). In agreement with the findings of Ranadine, Korgaonkar and Sahasrabudhe⁷, the initial disappearance yield for pyrimidines which lack a 5-methyl group, uracil and cytosine, is less than in acid solution, but saturation of the double bond remains a major reaction. However, with the pyrimidines which have a 5-methyl group, thymine and 5-methylcytosine, the initial yield for chromophore loss is zero. Since the amino group takes little part in the reaction (cf. uracil and cytosine) it is probable that with 5-methylcytosine, as has been reported previously for thymine, attack is occurring on the 5-methyl group, leaving the double bond unsaturated and the chromophore unchanged. The expected product, by analogy with thymine, is 5-hydroxy-methylcytosine.

The presence of a pentose group on the pyrimidine ring has a marked effect on radiolysis in alkaline solutions. Irradiation of the ribose compounds, uridine and cytidine (nucleosides), in 2 N sodium hydroxide results in an increase in optical density. Irradiation of ribose (and deoxyribose) alone in 2 N sodium hydroxide causes an increase in optical density approximately equal to that observed in uridine and cytidine with equivalent doses. It may be tentatively concluded, then, that the ribose unit successfully competes with the double bond of the uracil and cytosine units for the radiation-produced active species. Attachment of a phosphate to the pentose, as shown by results obtained from nucleotides (Table 1), has no appreciable effect. Irradiation of alkaline solutions of the nucleosides, thymidine and 5-methyldeoxycytidine, and the nucleotide, thymidylic acid, does not cause a change in optical density. This suggests that the 5-methyl group is more subject to attack than the deoxyribose unit. The relative sensitivity of the ribose and deoxyribose units in comparison with the sensitivity of the 5,6-double bond is shown by experiments with the nucleotides, cytidylic and deoxycytidylic acids. The former gives an increase in optical density, the latter a decrease amounting to an apparent initial chromophore disappearance yield of 0.4. Thus the ribose unit competes with the double bond for the attacking species more successfully than does the

deoxyribose; that is, in strongly alkaline solution ribose attached to a pyrimidine compound appears to be more sensitive to radiation than is deoxyribose, similarly attached.

Irradiation of neutral solutions of the various pyrimidine compounds gives results which are not grossly different from those observed in acid solutions.

From these results, it may be concluded that in acid solution the initial radiolytic attack occurs chiefly at the 5,6-double bond of the pyrimidine ring. Amino and methyl groups do not appear to be attacked, and the presence of a pentose or pentose phosphate unit diverts no more than 20 per cent of the attacking species from the double bond. In alkaline solutions, where the molecules are ionized, both methyl and ribose groups compete successfully with the double bond for the attacking species, that is, are more sensitive. Ribose appears to be somewhat more sensitive than deoxyribose when attached to cytosine. The phosphate group appears to play no important part in the initial radiolytic attack under any of the conditions reported here.

CHEMISTRY

Advances in Liquid Chromatography

THE development of liquid chromatographic techniques has been restricted because of the non-existence of sensitive detection systems. Apart from the tedious manual analysis of evaporation and determination by weight or titration the only available continuous method has been ultra-violet absorption. In this process, the sample, for example amino-acid, peptide or protein, is developed by an external reagent like ninhydrin to give strong absorption in the ultra-violet. This procedure is carried out at a single wave-length and is restricted to those samples with the required characteristic.

A detection system based on a moving wire has been developed which continuously monitors the effluent of a liquid chromatographic column¹. The principle of operation is similar to that reported by James, Scott and Ravenhill². The system is applicable to all relatively involatile organic compounds irrespective of structure, for example, fatty acids, amino-acids, peptides, lipids, steroids, etc. A great advantage is that the process is independent of the mobile liquid phase, which could be a mixture of hexane, benzene, ether and water and all the intermediate solvents as quoted in Trappe's elution table. At present this method has detected a concentration of 5 μ g triglyceride in 1 ml. of hexane. It is feasible that this performance can be improved.

The advantages of a continuous detection system possessing this high degree of sensitivity will be immed-

Table 1. INITIAL YIELDS (MOLECULES/100 eV ABSORBED) FOR THE DISAPPEARANCE OF THE PYRIMIDINE CHROMOPHORE GROUP ON EXPOSURE OF AQUEOUS SOLUTIONS, 2 N SODIUM HYDROXIDE, TO COBALT-60 γ -RADIATION

ately recognized by workers in liquid chromatography as being of value for the improvement of liquid columns.

Present sample injections are of the order 0.5–10 ml. With the improved sensitivity of the wire detector, injections of the order 10–100 μ l. will be sufficient for quantitative analyses. The reduction in sample size makes practical the use of high-efficiency micro or capillary columns for analytic separations. The high performance of these columns will give a reduction in analysis time by reducing column length and/or increasing the velocity of the moving liquid phase, resulting in an analysis time comparable to a gas-liquid chromatographic separation.

A liquid-chromatographic column requires a stationary phase which can be either solid (for example, alumina, silicic acid) or liquid (for example, water). In using micro or capillary columns it will be necessary to select the operating conditions to minimize the loss of stationary liquid phase via column bleed. When the stationary phase is a solid, column bleed is negligible. The column is, therefore, stable, and can be used for many analyses.

Microstructure of Fibrous Sulphur

PRINS *et al.*^{1–4} have shown, using X-ray diffraction, that fibrous sulphur (S_8) is made up of a long-chained polymeric component (S_μ) together with a crystalline allotrope (S_γ). Prins *et al.*² have also proposed a model for the polymer in which the sulphur atoms are arranged in a helical structure with $3\frac{1}{2}$ atoms per turn; later, Prins and Tuinstra³ suggested the possibility of a spiral superstructure of these helices, with a longitudinal repeat distance of 78 Å.

The similarity between the molecular structure thus described and that of some synthetic carbon-chain polymers⁵ suggested to us that another feature sometimes found in drawn polymers, namely, the presence of a fibrillar structure as demonstrated by electron microscopy⁶, might also be observed in fibrous sulphur.

Sulphur fibres a few μ in diameter were therefore prepared by drawing directly from the melt, using a glass rod; the melt consisted of sulphur of 99.99 per cent purity, maintained at a temperature in the range 250°–300° C. These air-quenched fibres were first examined directly in the electron microscope. As expected, the effects of high vacuum and the heating action of the electron beam led to evaporation and partial destruction; during this process, however, it was possible to observe and record a characteristic macro-fibrillar structure in the specimen (Fig. 1). These macro-fibrils, of diameter about 2000 Å, appeared to resist evaporation longer than the rest of the specimen, which presumably consisted of S_8 . They also repelled one another laterally, probably as a result of electrostatic charging in the electron beam. This effect can be seen in an extreme form at A, in which a macro-fibril has broken away from the fibre along part of its length and bowed outwards.

In one or two cases these macro-fibrils could be seen to consist of bundles of fibrils, about 250 Å in diameter. At the edge of the fibre, single fibrils of about the same size extended perpendicularly to the surface (B, Fig. 1); it seems probable that they were held in this position by their electrostatic charge, which, in combination with the sublimation effect, produced stretching, thinning and eventual disappearance of the fibrils.

The surface of sulphur fibres prepared as already described was investigated by means of single-stage carbon replicas; carbon was evaporated directly on to the fibre surface, followed by removal of the sulphur by slow sublima-

tion *in vacuo*. The surface structure appeared to consist (Fig. 2) of fibrils running parallel to the length of the fibres with a diameter of 370 ± 10 Å. Some of these showed a still finer structure (A, Fig. 2), consisting of dark, approximately parallel lines about 80 Å apart. These may have been micro-fibrils, but the precise interpretation is not yet clear.

During the preparation of air-quenched specimens it was found that variations in melt temperature and strain rate could lead to the production of fibres with a wide range of mechanical properties; some permitted visco-elastic extension to very high ratios at low stress, while in others the stress rose rapidly until a fully stress-hardened relatively inextensible fibre was formed. This behaviour is typical of those synthetic polymers in which stress-induced crystallization occurs during drawing⁷.

In an attempt to obtain greater reproducibility, water-quenched fibres were made by pouring molten 99.999 per cent sulphur into cold water; it was found that, for a melt temperature of 250° C, these could always be fully extended and stress-hardened by hand at moderate strain rates.

In the as-quenched condition little or no surface structure was visible in the electron microscope, but fully stress-hardened fibres showed a well-developed fibrillar surface (Fig. 3), the fibrils having a mean diameter of 300 ± 25 Å. They were often curled, as though broken under tensile stress.

An exactly similar fine structure to that shown at A in Fig. 2 was also found, although the line spacing, at about 50 Å, was somewhat smaller.

The main difficulty in preparing single-stage carbon replicas of sulphur fibres lay in subliming the sulphur

Fig. 1. Transmission micrograph of air-quenched sulphur fibre A, macrofibril; B, fibrils ($\times 8,000$)

Fig. 2. Carbon replica of air-quenched fibre A, fine structure; B, replica distortion ($\times 20,000$)

Fig. 3. Carbon replica of water-quenched drawn fibre, showing fibrillar surface structure ($\times 12,000$)

sufficiently slowly to prevent distortion of the carbon film. At a pressure of 10^{-4} torr, a temperature of 60° – 80° C gave complete sulphur removal in 1 h, in most cases without replica distortion. Fig. 2 shows some examples (at B) of the type of distortion usually produced; the fibrillar structure is on a much finer scale, and is apparently unaffected.

It therefore appears that three distinct levels of sub-structure in fibrous sulphur can be detected in the electron microscope. The long polymer chains postulated from X-ray evidence are, we suggest, aggregated into fibrils 250–400 Å in diameter, perhaps via micro-fibrils 50–100 Å in diameter. These fibrils then bunch together into macro-fibrils 2000 Å in diameter. The nature of long carbon chain polymer fibres is by no means fully understood, particularly in regard to their crystallinity, and the study of similar fibres composed of a single element, sulphur, may help to throw some light on this problem.

This work was carried out during the tenure of a United Nations Fellowship by one of us (A.J.). We also thank the Sulphur Institute for a gift of high-purity sulphur.

Infra-red Emission Spectra of Minerals

THIS study was undertaken to explore the feasibility of measuring infra-red emission spectra of bulk, opaque minerals. As this involved the examination of the rough, irregular surfaces of bulk specimens at temperatures close to room temperature, emission methods using conventional spectrometers¹ were not applicable. The emittance of specimens near room temperature is too low to operate dispersion spectrometers.

A Block Model I-4T interferometer spectrometer was used, with the detector at about 30° . The theory and

operation of the instrument are described elsewhere^{2,3}. Repetitive interferometric spectra of specimens at about 40° were digitized and coherently added at a rate of 2 scans per second with a 'Coadder' (Block Engineering Co.) in order to enhance the signal. The cumulative spectrum was then processed with a wave analyser, to result in plots of emittance against wave-number. The resolution was 40 cm^{-1} and is shown at R in the figures. The ordinates are arbitrary and are displaced in Figs. 2 and 3 to avoid overlapping of spectra.

Fig. 1 shows the results of the coherent addition of spectra of asbestos, each plot except that marked 1 representing the summation of several individual scans. The spectrum 'grows' with increasing number of scans, so that detailed spectra can be obtained even though the emittance of the specimen is very low. Figs. 2 and 3 show other examples of interferometric infra-red emission spectra of homogeneous bulk mineral specimens. In each case the spectrum shown is the sum of multiple scans. Detailed structure is revealed, indicating the feasibility of developing the method for the direct examination of bulk specimens.

Fig. 1. Infra-red emission spectra of asbestos fibres. The number by each spectrum indicates the number of scans taken

Fig. 2. Infra-red emission spectra of bulk mineral specimens. The specimen and number of scans are: A, nodular turquoise from Arizona, 120; B, interior of turquoise nugget from Nevada, 180; C, jade, 60; D, Psilomane, 32

Fig. 3. Infra-red emission spectra of bulk mineral specimens. A, azurite; B, rhodocroite; C, muscovite; D, calcite. 120 scans were taken for each spectrum.

The emission was monitored from areas of about 1 cm diameter on the surface of each sample. The coherent addition of spectra, however, will permit examination of much smaller areas, so that inhomogeneous specimens or small homogeneous specimens could be examined.

Nitroso Formaldehyde

In recent papers by McGrath and McGarvey^{1,2} a new spectrum was reported and the carrier identified as the methoxyl radical. This spectrum, consisting of diffuse bands at 2064 Å, 2036 Å and 1999 Å, was obtained from the flash photolysis of methyl nitrite. Under presumably adiabatic conditions McGrath and McGarvey found that the spectrum appeared at short delay and the intensity increased to a maximum within 2.5 msec.

We find, under isothermal conditions using a 2600 J flash, that the spectrum reaches maximum intensity 70–100 μsec after flashing and that a fourth band at about 1985 Å is also present. The latter band appears to be present in McGrath and McGarvey's photograph but is partially obscured by a group of silicon reversal lines.

We feel that the identification of the spectrum is erroneous since it can be obtained by flashing—in the presence of nitric oxide and excess nitrogen—formaldehyde, formic acid, methyl formate, acetaldehyde or glyoxal. In those cases investigated in detail, namely, glyoxal and formaldehyde, the spectrum reached maximum intensity about 60 μsec after flashing and slowly disappeared over a period of 100 msec. In experiments with glyoxal, an

aqueous sodium nitrite filter with a cut-off at 4000 Å was used to ensure that excitation occurred only through the 4000–5000 Å bands of glyoxal.

Further confirmation that these spectra arise from a common carrier was found by flashing fully deuterated formaldehyde with nitric oxide in the presence of nitrogen and also fully deuterated methyl nitrite. In both cases the spectra observed were the same. The effect of deuteration on the 2064 Å band was a 6 Å shift to shorter wavelength and with sharpening and apparent splitting. Little difference was noted in the 2036 Å band, but the 1999 Å band disappeared and the 1985 Å band was sharper and more intense. No new bands were observed when CHDO was flashed with nitric oxide. However, this does not necessarily prove the existence of only one hydrogen atom in the carrier since the small extent of the shifts coupled with the diffuse character of the bands could well obscure new bands.

The compounds giving rise to this spectrum are all known to produce formyl radicals on flashing^{3,4}. This was confirmed in the case of glyoxal but it was found that formyl radicals could not be observed when mixtures of glyoxal and nitric oxide were flashed isothermally. In this case the spectrum of HNO appeared at 14 μsec delay, reached a maximum at about 100 μsec then decayed over a period of 46 msec. Both glyoxal and nitric oxide were depleted to a small extent by the flash.

Continuous photolysis of 40 mm glyoxal and 80 mm nitric oxide at 18° C, using a 600-W medium pressure mercury arc, resulted in the decomposition of 33 mm glyoxal and the reaction of 20 mm nitric oxide after 90 min photolysis. The major gaseous products were carbon monoxide and nitrogen with small amounts of nitrous oxide and nitrogen dioxide (tentatively identified) and a trace of carbon dioxide. In the absence of nitric oxide the same amount of glyoxal (33 mm) was decomposed in 15 min. The gaseous products in this case were carbon monoxide and a trace of hydrogen as found by Norrish and Griffiths⁵.

The flash photolysis experiments provide reasonably strong evidence that the 2064–1985 Å spectrum is that of CHONO. Light absorbed by methyl nitrite at its maximum (2150 Å) corresponds to 130 kcal/mole, while only 39 kcal/mole⁶ is required to break the O–NO bond. Some of the excess energy may appear as activation of CH₂O, which could undergo reactions (2) and (3):

It is presumed that formyl radicals generated by flashing the other compounds giving rise to the 2064–1985 Å spectrum also react as in (3).

The formation of HNO may be ascribed to the following two reactions, the latter being similar to that proposed by Fischer and Buchanan⁶ for the unimolecular decomposition of formyl fluoride:

The formation of nitrogen, nitrous oxide and nitrogen dioxide from the photolysis of glyoxal/nitric oxide mixtures is similar to the results obtained by Strausz and Gunning⁷ for the photolysis of formaldehyde/nitric oxide mixtures. They proposed that reaction (4) was followed by reactions (6), (7) and (8):

If our identification of the spectrum is correct, CHONO may be removed by a similar reaction scheme, with reaction (5) as the primary decomposition reaction.

One of us (I. M. N.) was supported in this work by a scholarship from the Public Service Board of Australia.

Use of 'Sephadex' Gel for the Estimation of Molecular Weight of Humic Substances in Natural Water

THOUGH little is actually known about the shape of humus molecules, and only a few experiments have been described^{1,2} on the fractionation of humus on 'Sephadex' gel (Pharmacia, Uppsala, Sweden), there is strong evidence or the existence of a relationship between the elution rate through the 'Sephadex' column and the molecular weight^{3,4}.

In the course of studies on the nature of the soluble humic substances that cause the brown-yellow colour of Norwegian surface-water, 'Sephadex' gel has been used in attempts to fractionate and characterize these substances according to their molecular size.

The molecular exclusion properties of the different gel types are reported by the manufacturers of 'Sephadex' to be as follows: 'Sephadex G-50' excludes solutes with molecular weights exceeding 8,000–10,000; correspondingly 'G-75' excludes solutes with molecular weights greater than 10,000–50,000, whereas with grades 'G-100' and 'G-200' the lower molecular weight limits for complete exclusion are 100,000 and 200,000 respectively. The molecular weights of humus reported in the literature vary from 600–300,000 (ref. 5).

Water from a typical moorland area was filtered through glass fibre pads (Whatman 'F/A') and concentrated by vacuum evaporation (400:1) at 35° C. During concentration, approximately 18 per cent of the total dry matter of the concentrate was precipitated. This was removed by filtration before proceeding further. Results of some analyses of the water sample and its concentrate are shown in Table 1. Portions of the filtered concentrate were passed through columns of 'Sephadex' and were eluted with distilled water containing a trace of thymol to prevent bacterial growth. The fractions obtained were analysed for colour, total iron, hardness (EDTA method) and permanganate oxidation value (COD).

Attempts to isolate small humus molecules (mol. wt. < 8000), by means of lower 'Sephadex' grades 'G-25' and 'G-50', were unsuccessful and resulted in an irreversible desorption or coagulation, visible as brownish-coloured flocs all through the bed material. As far as I am aware no irreversible phenomenon of this kind has previously been reported^{6,7}. Flotation experiments with gel 'G-50', containing the flocculated humus, seem to indicate that the phenome-

Table 1. COMPOSITION OF FILTERED MOORLAND WATER BEFORE AND AFTER CONCENTRATION

Date	Colour mg Pt/l.	Filtered water				Hardness (total) mg CaO/l.	Concentrated filtered water	
		GOD (K ₂ Cr ₂ O ₇) mg O/l.	Fe++ μg/l.	Fe+++ μg/l.	pH		pH	Evaporation residue mg/ml.
May 19 62	13 1	90	12	5 4	5.9	4.6	10.5	

non is the result of coagulation, probably caused by desalting due to the small negative charge on the 'Sephadex'. When the humus concentrate was applied to columns of 'Sephadex G-75' and 'Sephadex G-100' the separation shown in Fig. 1 a and 1 b resulted. In each case the humic substances are separated into two peaks with distribution coefficients (K_D) of 0 and approximately 1, respectively. The fractions representing peak C (Fig. 1 b) were evaporated in vacuum to a suitable volume and filtered through a column of 'Sephadex G-200'. This filtration (Fig. 1 c) resulted in only one peak with distribution coefficient 0.1. These experiments indicate that apart from the precipitate formed during concentration the organic matter in typical moorland water consists of at least two types of humic substances that differ considerably in molecular size. The larger molecular fraction probably has a molecular weight of between 100,000–

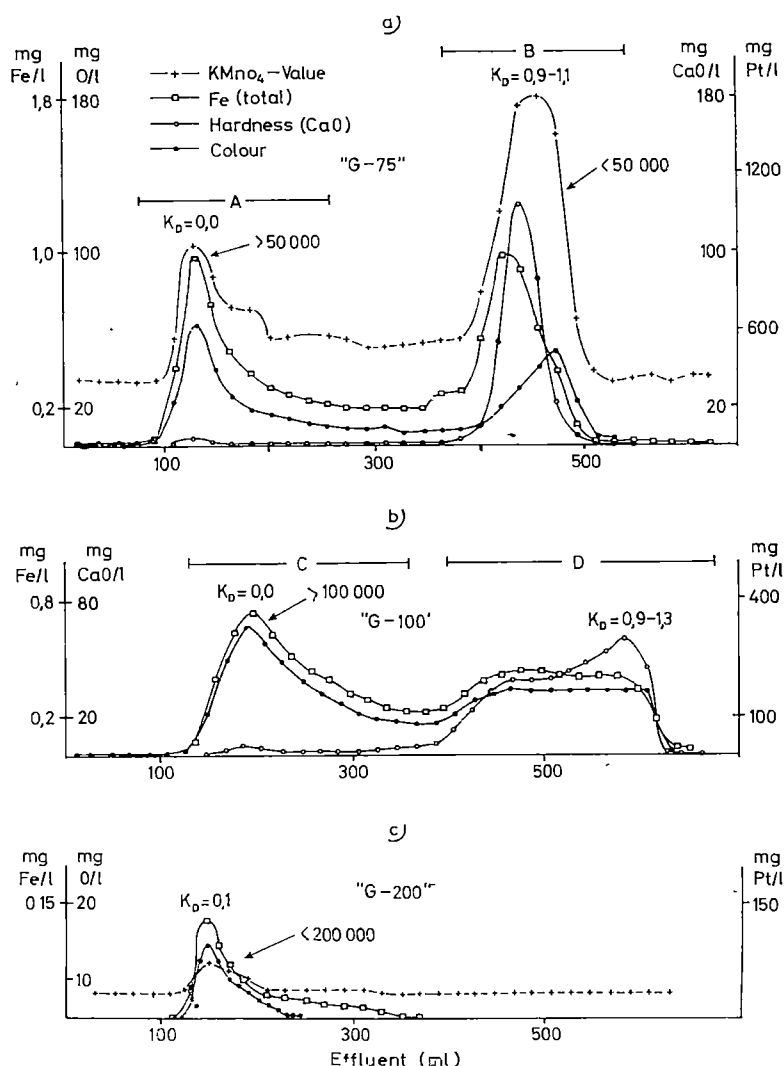

Fig. 1 Fractionation of water-soluble humic substances on 'Sephadex' with distilled water as eluant.
(a) 'Sephadex G-75'. Column dimensions, 49 × 3.3 cm. Sample: 4 ml. water concentrate containing 42.3 mg solute. (b) 'Sephadex G-100'. Column dimensions, 47 × 3.6 cm. 200,000 and the smaller possibly below 10,000. Both these types are believed to consist of organic complexes of ferrous iron⁸. It is interesting to note that one of these molecular types contains calcium. This has been confirmed by continuous electrophoresis experiments, which indicate that about 3/4 of the calcium in the fractions of peak *B* (Fig. 1 *a*) is associated with the coloured iron complexes. The manner in which this calcium is bound to the humus is unknown.

Errors in the Calculation of Surface Area and Average Pore Radius

In the determination of surface areas from adsorption data the area of the adsorbed molecules A_m is usually calculated from the liquid density, assuming hexagonal close packing in the liquid state on the surface, namely:

$$A_m = 1.091 \left(\frac{M}{d_l N} \right)^{\frac{2}{3}} \quad (1)$$

where M is the molecular weight of adsorbate, d_l is liquid density in g/cm³, N is Avogadro's number.

The constant 1.091 is a packing factor to account for hexagonal close packing. This calculation assumes that the molecule only covers an area on one flat, or almost flat, surface. In very small pores, which occur in certain zeolites, charcoals, and silica², this is not true. To take an extreme case, if only one molecule can fit into the pore touching the walls (as shown in Fig. 1), it actually covers an area of $4\pi r^2$, the area of the cylinder into which it fits,

The area of the triangle is the area that three 60° angle segments of the projected area of one molecule cover; that is, half the total projected area. Area of triangle = $\frac{1}{2} \times \text{base} \times \text{height} = \frac{1}{2} \times 2r \times \sqrt{3}r = \sqrt{3}r^2$. Therefore area covered by a molecule = $2\sqrt{3}r^2$. Area covered by two molecules = $4\sqrt{3}r^2$.

$$\frac{\text{True area}}{\text{Apparent area}} = \frac{4\pi r^2}{2\sqrt{3}r^2} = \frac{2\pi}{\sqrt{3}} = 3.63$$

$$\frac{\text{True area}}{\text{Apparent area}} = \frac{8\pi r^2}{4\sqrt{3}r^2} = \frac{2\pi}{\sqrt{3}} = 3.63$$

Fig. 1. Apparent and actual molecular coverage in molecular sized pores

where r is the radius of the pore. The simple adsorption theory assumes it to cover an area of $2\sqrt{3}r^2$. Thus the actual area is $\frac{2\pi}{\sqrt{3}}$ ($= 3.63$) times the apparent area.

If the pore is two molecular diameters wide, the factor is again 3.63. For increasing pore size the factor will decrease quickly to unity, but substances with pore approaching molecular size will show apparent surface areas which are really too low. Silica samples of this type have been shown to have areas of the order c 300 m²/g or less¹ compared with commercial silica gels with areas of 600–700 m²/g. This is the reverse of what might have been expected assuming a similar total pore volume in the two types of silica.

Average pore radius is often calculated from total pore volume V_p cm³/g and surface area S cm²/g. Assuming the pores to be open cylinders of radius \bar{r}_p cm, then

$$\bar{r}_p = \frac{2V_p}{S} \quad (2)$$

$$\text{However } V_p = \frac{X_T}{1,000d_l} \text{ cm}^3/\text{g} \quad (3)$$

where X_T is adsorption at saturation in mg/g and d_l is density of liquid adsorbate in g/cm³

$$\text{Also } S = \frac{X_m N A_m}{1,000 M} \text{ cm}^2/\text{g} \quad (4)$$

where X_m is monolayer adsorption in mg/g and the other terms are as previously defined.

$$\text{Then } \bar{r}_p = \frac{2X_T}{1,000d_l} \frac{1,000 M}{X_m N A_m} = \frac{X_T}{X_m} \frac{2M}{d_l A_m N} \text{ cm} \quad (5)$$

Substances with very fine pores, similar to those already mentioned, give type I adsorption isotherms with very sharp 'knees'. In these cases the monolayer capacity (calculated by the use of the Langmuir equation) is found to be very nearly equal to the total adsorption. Thus X_m and X_T in equation (5) are equal and this leaves \bar{r}_p as a constant. Substituting the values for nitrogen adsorption

$$\bar{r}_p = \frac{2 \times 28}{0.808 \times 6.03 \times 10^{23} \times 16.2 \times 10^{-16}} = 7.08 \times 10^{-8} \text{ cm} \quad (6)$$

Thus whatever the true pore size might be, a value less than about 7 Å radius cannot be obtained from adsorption data. This error in radius is connected with the error previously described in that 16.2 Å is not the area covered by the nitrogen molecule in these pores.

Combining equations (1) and (5), cancelling X_m and X_T and ignoring the packing factor gives

$$\bar{r}_p = 2 \left(\frac{M}{d_l N} \right)^{\frac{1}{3}}$$

where $\left(\frac{M}{d_l N} \right)^{\frac{1}{3}}$ may be taken to be approximately equal to the molecular diameter D_m . Thus in general pore radius never appears less than twice the adsorbate diameter for calculation. This type of error has also been shown for very fine-pored silica² where radii appear always 7–10 Å by calculation based on nitrogen adsorption, whereas molecular sieve effects show the pores to be mainly 3.5 to 4.8 Å in diameter³.

BIOCHEMISTRY

Correlation of the Binding to DNA Loops or to DNA Helices with the Effect on RNA Synthesis

RECENT investigations have revealed that template DNA is found natively in the form of single-stranded loops during the active transcription of selected portions of the genome in higher organisms^{1,2}. Conversely, during repression of such transcription the DNA is found natively in the form of double-stranded helices^{1,2}. A variety of organic molecules which function *in vivo* as inhibitors or stimulators of RNA synthesis within pre-selected portions of the genome³ have been shown to be capable of a reversible physical binding to DNA *in vivo* or *in vitro*. Each of these inhibitors or stimulators binds preferentially to either single-stranded or to double-stranded DNA. In every case for which adequate data are available (Table 1), a strong correlation exists between the form of DNA preferred for binding and the effect of the ligand on DNA synthesis within pre-selected portions of the genome. These strong correlations suggest that such ligands may exert their characteristic effects on RNA synthesis by preferentially stabilizing either the inactive helical form or the active loop form of DNA^{2,10} in the equilibrium:

The mechanisms of such preferential binding to either double-stranded helical DNA or to single-stranded loop DNA are little understood. Preliminary thermodynamic analyses have revealed that the equilibrium between the helical and the loop forms of DNA can be shifted during binding by an effect of the ligand on one or more of the physical forces existing within the DNA-solvent system. These forces include: (a) the hydrophobic solute-solvent interactions between DNA and water¹⁹; (b) the hydrogen bond interactions between the complementary bases of opposing DNA strands²⁰; (c) the electrostatic charge interactions between the phosphate groups of the same or opposing DNA strands²¹; (d) the stacking (van der Waal's) interactions between the successive bases of the same or opposing DNA strand²². In addition, the ability of particular ligands to (e) cross-link opposing DNA strands²³ or to (f) fit sterically into certain regions of the DNA molecule²³ is of importance in the inhibition or stimulation of RNA synthesis. Thus, both histone-type inhibitors and actinomycin-type inhibitors bind preferentially to double-stranded helical DNA by utilizing properties (e) and (f)²³. In addition, histones alter physical force (c)³, while actinomycins may alter forces (a), (c) and (d)⁶. By contrast, both testosterone-type stimulators and oestrogen-type stimulators bind preferentially to single-stranded loop DNA by utilizing property (f)²⁴, and by altering physical forces (a) and (d)²⁴. Before such inhibitors or stimulators can bind to DNA and alter the rates of RNA synthesis they must often be first concentrated within the particular sensitive tissue by specific, non-DNA binding agents^{13,25}.

All the foregoing inhibitory or stimulatory ligands (Table 1) except complementary RNA are molecules which are capable of reacting with all portions of the DNA genome non-selectively. RNA by contrast is capable of a selective interaction with specific portions of the DNA genome¹⁷. It is this selective ability which appears to be the basis for its role as the agent of specific de-repression of RNA synthesis during selective transcription of the genome^{1,2,18}. In a similar fashion, polyoma viral DNA binds preferentially to single-stranded host DNA²⁶. The result of such oncogenic viral DNA interaction with the host DNA genome is a de-repression of host DNA synthesis and of host enzyme synthesis^{27,28}. A concurrent selective de-repression of host RNA synthesis is also likely²⁷.

This work was carried out during the tenure of a research career development award (CA-17857) from the U.S. Public Health Service.

Isolation and Amino-acid Sequence of β -LPH from Sheep Pituitary Glands

SEVERAL adenohipophyseal hormones have been demonstrated to possess *in vitro* lipotropic activity; these include growth, adrenocorticotrophic, thyrotrophic, α -melanocyte-stimulating and β -melanocyte-stimulating hormones. Recently, Rudman, Astwood and their colleagues reported the preparation of Fraction H, peptides I and II, and showed these preparations to be lipotropic agents^{1,2}.

In the course of investigating a simplified procedure for the isolation of ACTH from sheep pituitary glands, we have obtained a lipotropic peptide³ which is chemically distinct from ACTH and other known adenylohypophyseal hormones. In this communication, we wish to describe the isolation of another lipotropic peptide (designated as β -LPH) from sheep pituitaries. The complete amino-acid sequence of β -LPH will also be presented here.

The procedure for the isolation of the sheep β -LPH was similar to that previously described³, except that acid-acetone extraction, sodium chloride precipitation and dialysis were carried out at 0° C. In addition, the solution was adjusted to pH 8 before dialysis and the dialysed fluid was maintained at this pH. The insoluble material encountered during dialysis was centrifuged off and the clear supernatant fluid was chromatographed on the carboxymethyl-cellulose (CMC) column. The final step of purification involved chromatography on a cation exchanger IRC-50 column which has been equilibrated with 0.01 M ammonium acetate buffer of pH 4.6. The final product was shown to be homogeneous by various criteria including exclusion chromatography on 'Sephadex G-75', paper chromatography, ultracentrifugational analyses, and terminal amino-acid studies.

The amino-acid content in molar ratios as determined by the automatic amino-acid analyser⁴ is as follows: Lys₁₀, His₂, Arg₄, Asp₄, Thr₄, Ser₅, Glu₁₆, Pro₅, Gly₈, Ala₁₃, Val₂, Met₂, Ileu₁, Leu₄, Tyr₃, Phe₃, Try₁. The calculated molecular weight based on this composition is in good agreement with that obtained by sedimentation equilibrium investigations. Terminal analysis using the carboxypeptidase procedure indicates the sequence . . . Gly-Glu(NH₂) at the COOH terminus. By means of the phenylisothiocyanate method, the NH₂-terminal sequence Glu-Leu . . . was established.

Five peptide fragments were obtained by the reaction of β -LPH with cyanogen bromide⁵ and purified by CMC column chromatography. Amino-acid and terminal group analyses revealed that the five peptide fragments were derived from the parent molecule with the amino-acid sequences as follows: I, 1-47; II, 1-65; III, 66-90; IV, 48-65; and V, 48-90 (Fig. 1). After these fragments were subjected to enzymatic digestions with pepsin, trypsin and chymotrypsin; the digests were purified by zone electrophoresis on paper followed by paper chromatography. The purified peptides were analysed for amino-acid composition, NH₂- and COOH-terminal residue. Most of the purified peptides were also subjected to the step-wise degradation procedure of Edman⁶. From these results, the complete amino-acid sequence of β -LPH was proposed as shown in Fig. 1.

It is of great interest to note the presence in β -LPH of a core, Met-Glu-His-Phe-Arg-Try-Gly, a sequence identical with that held in common by adrenocorticotrophic and melanotropic hormones from various species. In addition, the amino-acid sequence 37-58 in β -LPH is identical to that of human^{7,8} β -MSH except that amino-acid residues in positions 42 and 46 are serine and lysine instead of glutamic acid and arginine as in the case of the human hormone.

The detailed account of this work will be published in the *Proceedings of the Sixth Pan-American Congress on Endocrinology*. This work was supported in part by grant (G-2907) from the National Institutes of Health U.S. Public Health Service. L. B. and M. C. wish to acknowledge fellowships from the Guggenheim Foundation and the Jane Coffin Childs Memorial Fund for Medical Research respectively.

Reactivity of the ϵ -Amino Group of Collagen

In view of the frequency with which the results of Bowes and Moss¹ are quoted as indicating that only about 60 per cent of the ϵ -amino groups of lysine in collagen are available for reaction with fluorodinitrobenzene (FDNB), we should like to put on record the following observations.

Out of 27 millimoles lysine per 100 g collagen², 13-14 millimoles were recovered as ϵ -DNP-lysine. After correction for hydrolytic losses based on recovery of ϵ -DNP-lysine added to collagen and hydrolysed under the same conditions, this represents reaction with 17 millimoles per 100 g. Analyses by the Moore and Stein³ procedure revealed only 3 to 4 millimoles of lysine in the DNP-protein, indicating much more extensive reaction and leaving 10-11 millimoles of ϵ -DNP-lysine unaccounted for. This, together with the relative constancy of the amounts of ϵ -DNP-lysine recovered regardless of the pre-treatments given to the collagen, led to the suggestion that "failure to account for all the lysine as the ϵ -DNP derivative was not primarily due to non-reactivity of the lysine to FDNB" but to the fact that " ϵ -DNP-lysine is much less stable to acid when combined in the collagen than when present as the free amino-acid".

Since that time various values have been reported for the availability of ϵ -amino groups in skin collagen, for example, Sykes⁴, 70-80 per cent; Solomons and Irving⁵, 64-70 per cent; Hormann⁶, 90 per cent; Hallsworth⁷, up to 70 per cent; and Courts⁸, 90-100 per cent in gelatine derived therefrom. Using a procedure based on that of Courts we ourselves have been able to account for all the lysine in DNP-collagen as ϵ -DNP-lysine⁹.

It is possible that variations in reactivity reported are, at least in part, related to the difficulties involved in establishing a reliable correction factor for losses of

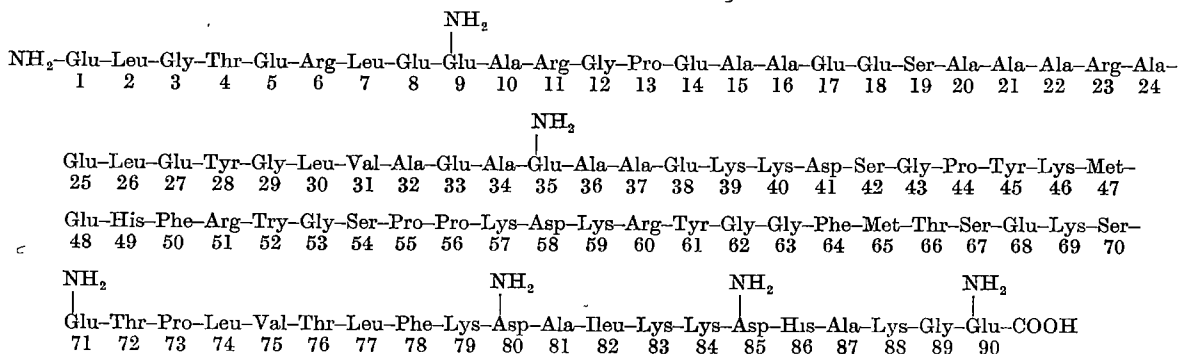

Fig. 1. The amino-acid sequence of the sheep pituitary β -LPH

DNP-lysine during hydrolysis and separation. There seems to be little evidence that under favourable conditions reaction of FDNB with ϵ -amino groups of collagen does not approach completion.

Antiviral Action of Oxidized Spermine— Inactivation of Plant Viruses

SPERMINE, $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$, a naturally occurring polyamine, is oxidized by purified serum amine oxidase as follows (ref. 1):

Oxidized spermine (OS) was shown to inhibit the growth of *Mycobacterium tuberculosis*^{2,3}, *Escherichia coli*, and *Staphylococcus aureus*⁴, and to inactivate various other bacteria⁵ and bacterial viruses⁶. It was therefore of interest to study also the effect of OS on several plant viruses.

The following virus inocula were used: Potato virus Y (PVX) (a yellow strain) was purified from *Nicotiana glutinosa* L. leaves, by rate-zonal, density-gradient centrifugation, after charcoal adsorption⁷. Tobacco mosaic virus (TMV) was purified from *N. tabacum* L. leaves by differential centrifugation⁸, or used in the form of a crude extract. Alfalfa mosaic virus (AMV) was obtained as a crude extract from *N. glutinosa*. The crude extracts, TMV and AMV, were prepared by grinding 0.5 g leaves in ml. 0.06 M phosphate buffer pH 7.0; TMV extract was further diluted 1:25 in the same buffer. OS was prepared by oxidation of spermine hydrochloride with purified def-plasma amine oxidase⁶.

The reaction mixture, containing OS and virus, was incubated for 90 min at 37° C, and diluted to 4 ml. with 0.6 M phosphate buffer at pH 7.0. In the control, OS was replaced by an equal volume of phosphate buffer, or phosphate buffer and amine oxidase.

Test and control mixtures of TMV and AMV were assayed by rubbing with gauze pads on 16 opposite half leaves of *N. glutinosa*, or *Phaseolus vulgaris* var. 'Pinto', respectively, previously dusted with carborundum. PVX was assayed on the opposite leaves of *Gomphrena globosa*. Lesions were counted 3–5 days after appearance and the results were analysed by the 'sign-test'⁹.

With all three viruses tested, either purified or as crude extracts, OS caused a significant reduction in lesion number (Table 1). Residues of amine oxidase in the reaction mixture did not affect infectivity of TMV.

Table 1. INACTIVATION OF TMV, PVX AND AMV BY OXIDIZED SPERMINE (OS)

Virus	Reaction mixture ml. virus	ml. OS (600 µg/ml.)*	Average No. of lesions per half leaf†	Reduction of lesions No. in log
TMV, purified (0.02 mg/ml.)	0.2	0.2	8	95§
TMV, purified†	0.2	0.2	31	211§
TMV, crude extract	0.2	0.8	3	58§
PVX, purified	0.2	0.2	1	13§
AMV, crude extract	0.4	0.4	0.13	5.69§

* Based on the amount of spermine added to the original incubation mixture.

† The number of lesions per half leaf represents the average of 16 half leaves.

‡ In this experiment the control contained amine oxidase at same concentration as OS.

§ Significant at 1 per cent level.

When increasing concentrations of OS were incubated with a constant concentration of TMV (0.02 mg/ml.), maximum activity was observed around 100 µg OS in 0.6 ml. of the reaction mixture (Fig. 1). The rate of viral inactivation by OS increased by prolonging the incubation of the reaction mixture (Fig. 2).

The inactivating effect was not eliminated when free OS was removed from the incubated reaction mixture by 2 cycles of centrifugation at 105,000g for 1 h, washing and resuspending the TMV containing pellets in buffer. The rate of inactivation in these suspensions was highly significant and similar to that of those virus samples which were inoculated together with OS (Table 2). This would indicate that OS is bound to the viruses, which are then inactivated, and does not act on the host. No deleterious effect of OS on the leaves was observed.

OS was found to inactivate 3 different plant viruses *in vitro*; a rigid rod type (TMV), a flexible rod (PVX) and a

Fig. 1. Effect of concentration of OS on TMV inactivation

Fig. 2. Effect of incubation time on TMV inactivation

Table 2 ANTIVIRAL EFFECT OF BOUND OXIDIZED SPERMINE (OS)

Incubation time (min)	Inoculum	Average No. of lesions per half leaf		Reduction of lesion No. in log
		OS	Control	
90	OS+TMV	36	73†	0.306
	TMV*	10	25†	0.402
180	OS+TMV	3	62‡	1.408
	TMV*	3	42‡	1.140

* Free OS was removed by ultra-centrifugation and washing.

† Significant at 5 per cent level.

‡ Significant at 1 per cent level.

spherical virus (AMV). This suggests, though further proof is necessary, that OS may inactivate a broader range of plant viruses. The inactivation *in vitro* is a function of the incubation time and concentration of OS. This suggests that the inactivation is due to a chemical interaction. It is not unlikely that this chemical interaction is a reaction between OS and viral nucleic acids. Such a reaction has previously been proposed to explain the inactivation of T_4 coliphages by OS (ref. 10).

Maintenance of *Escherichia coli* and the Assimilation of Glucose

It has been shown^{1,2} that bacteria require a threshold level of an energy source for maintenance without growth. However, there is a possibility that the thresholds observed might represent some form of concentration requirement for permeability. Thus it is desirable to demonstrate directly the uptake of glucose fed at or below the threshold level. Any glucose assimilated in the absence of growth can then be correlated only with a maintenance requirement for a carbon-energy source.

Cultures of *Escherichia coli* B were grown, collected and washed as previously described¹, providing cells in the log phase of growth, keeping them cold to avoid uncontrolled starvation and maintaining a relatively constant osmotic environment. Suspended cells were then distributed among 15 experimental tubes so that each tube contained 7×10^8 cells per ml. in 10 ml. of the salt medium without glucose. Each tube contained 2.1 mg cells on a dry basis. One set of 5 tubes served as the starvation control receiving no exogenous energy source, another set of 5 tubes received unlabelled glucose, and the third set of 5 tubes received uniformly labelled glucose (glucose- $U^{14}C$). Glucose was fed to the appropriate tubes every 6 h at a level of 0.28 μ moles in 0.10 ml. of salt medium, a rate of 0.022 μ mole/mg cells/h. The radioactive glucose was so diluted with unlabelled glucose as to provide 7,700 counts/min/0.28 μ mole. The control group received an equivalent

volume of salt medium. Every other day one tube from each series was removed for plate count, turbidity measurement and determination of radioactivity. Methods for plate counts and turbidity measurements have been described elsewhere³, representing rather minor modifications of standard methods adopted to improve reproducibility.

To determine the radioactivity of incubated cells, 7-10 ml. aliquots of the cell suspensions were withdrawn from each tube and centrifuged for 10 min in a 'Serval' motor SS-1 at 1,800g and 4° C. The supernatant solution was discarded, and the pellet of cells washed twice by suspending in 5-ml. portions of salt medium and re-centrifuging as above. The cells were washed a third time with 5 ml. distilled water to improve counting efficiency removing salts from the residue. The resulting pellet of cells was re-suspended in 0.1 ml. distilled water and transferred with a micropipette to a rectangular piece of Whatman No. 1 filter paper (3.5 x 2 cm). A continuous current of warm air facilitated drying. Both the tube holding the cell suspension and the micropipette were rinsed three times with 0.5-ml. portions of distilled water and the washings were evaporated on the same paper. Lastly, each paper was placed upright in a 20-ml. vial and dried at 100° C for 1 h. The radioactivity of each sample was counted in a liquid scintillation system⁴.

Fig. 1 reveals that constancy of turbidity resulted from the periodic feeding of the small amount of glucose. Since turbidity records both dead cells and cellular debris, loss of cells or leakage of internal materials must have been limited for growth of other cells. Therefore, the threshold level reported earlier¹ does in fact represent a maintenance rather than a permeability requirement. Because the rate of feeding was too low for growth, the added glucose could have been completely oxidized to carbon dioxide and

Fig. 1. The incorporation of carbon from glucose- $U^{14}C$ and the maintenance of turbidity in suspensions of *E. coli*. All suspensions initially contained 7×10^8 cells/ml. These data are adjusted for the volume changes resulting from the additions made to the individual suspensions. Evaporation was prevented by use of tightly sealed culture tubes which were opened every 6 h both for the appropriate additions and to replenish the oxygen supply. Δ , Radioactivity of cells fed glucose- $U^{14}C$; \circ , turbidity of cells fed glucose- $U^{14}C$; \times , turbidity of cells fed unlabelled glucose; \square , turbidity of starved cells.

Fig. 2. Maintenance of viability on adding glucose to suspensions of *E. coli*. These data were obtained by plate counts made on aliquots of the suspensions described in the legend of Fig. 1. \circ , Fed glucose- $U^{14}C$; \times , fed unlabelled glucose; \square , starved cells.

ater. However, carbon from the glucose was assimilated to cellular components.

The corresponding Fig. 2 demonstrates the preservation viability in the cell suspensions fed glucose. Obviously a low level of radioactivity had no biological effect within the experimental period. Carbon from glucose was continually accumulated (Fig. 1) with a declining fraction tained as might be expected. After two days, 19 per cent the radioactivity fed was present in the cells while the action had dropped to 13 per cent of the much larger tal fed in ten days. Apparently glucose was utilized ore or less normally. Certainly it entered the cells and as partly assimilated and retained without concomitant owth.

PHYSIOLOGY

Hydrolysis of Disaccharides during Absorption by the Perfused Small Intestine of Amphibia

ALTHOUGH it is now generally conceded that disaccharides may be absorbed intact at appreciable rates from the lumen of the small intestine, as found for maltose by Waymouth Reid in 1901, very little is known about the factors which affect the process. It is established that in mammals, including human subjects, disaccharides such as lactose, sucrose and maltose undergo hydrolysis at some site in or on the mucosal cells and not in the intestinal lumen¹⁻⁴. We have now investigated the absorption of some disaccharides by the small intestine of some Amphibia using a system for the perfusion of the mesenteric vascular bed.

In this system the vascular perfusion was used to control the ionic composition of the sub-mucosal faces of the absorbing cells and to carry away for collection the material extruded from these cells. The oxygenation of the mucosal epithelial layer was achieved by the recirculation of bicarbonate-Ringer through the lumen of the intestinal segment by means of a gas lift (equilibration gas, 95 per cent oxygen, 5 per cent carbon dioxide) in a manner similar to that used for mammalian intestine⁵. The vascular perfusion was maintained by pumping bicarbonate-Ringer containing 1 g/100 ml. bovine serum albumin and equilibrated with 95 per cent oxygen, 5 per cent carbon dioxide through a nylon cannula (1 mm outer diam., 0.5 mm inner diam.) inserted through the systemic aortic arch into the coeliac-mesenteric artery. The vascular effluent was usually collected as a fluid comprising exudate from the cut mesenteric veins together with the 'sweat' extruded from the serosal surface of the perfused segment which is immersed in liquid paraffin. In some experiments the portal vein was also cannulated and the venous effluent collected separately. The rate of arterial perfusion at 26° C was of the order of 1 ml./min/g wet weight about 300 μ l./min for each intestine). Glucose was measured by use of *tris*-buffered glucose oxidase as described by Dahlqvist⁶.

With either glucose or maltose (initial concentration 1 mg/ml.) present in the mucosal fluid of intestine from *Rana pipiens*, it was found that the rates of appearance of glucose in the vascular effluent are almost the same (Table 1). In *R. pipiens* we also found similar evidence

for a trehalase activity which results in a vascular appearance rate of glucose similar to that from maltose. Lactase and sucrase appear to be absent. On the same basis, maltase and trehalase are also present in the small intestine of *R. temporaria* and of *Bufo vulgaris*. The small intestine of these two species also appears to be deficient in lactase and sucrase activity.

During these investigations, little disaccharidase activity was found in the mucosal fluids. When Ringer which contained maltose and had been circulated through the intestinal lumen for 1 h. was removed and incubated at 26° C the further rise in glucose concentration could be used to estimate the maltase activity in solution. In a series of eleven experiments on *R. pipiens* it was found that only 7.2 per cent of the total maltase activity of the preparations was in solution in the luminal fluid after luminal circulation for 1 h.

By measuring separately the rate of appearance of glucose in the vascular effluent and in the mucosal fluid it was possible to examine simultaneously the effects of differing maltose concentrations on the total rate of disaccharide hydrolysis and on the rate of glucose appearance in the vascular effluent. At concentrations below 5.56 mM these processes appear to conform to Michaelis-Menten type kinetics and hence it is possible to calculate an affinity constant (K_m) and a maximum velocity constant (V) for each. In Table 2 are given representative values of these parameters for maltose and for glucose transport into the vascular effluent from luminal solutions of maltose for specimens of *R. pipiens* of a different batch from those from which the data in Table 1 were derived. Also included in Table 2 are the values of K_m and V for glucose transport into the vascular effluent from luminal glucose solutions. When these are compared with the corresponding values for maltase it is seen that the values (in molar units) of the constants for the enzyme are greater than those for the glucose transport process. In other words, the rate of hydrolysis of maltose by the enzyme is not rate-limiting to transfer of glucose into the vascular effluent at high concentrations of the disaccharide in the intestinal lumen. On the other hand, the mechanisms underlying the transport of glucose into the vascular effluent are saturated at lower molar concentrations than the disaccharidase. In accord with these findings, the fraction of glucose liberated from the maltose by the maltase, and which appears in the vascular effluent, decreases as the concentration of the disaccharide in the lumen is increased. At low concentrations of the disaccharide the efficiency of capture of the liberated glucose molecules is remarkably high, no hexose liberation to the luminal circulation being detectable in some experiments using *Bufo vulgaris* (Fig. 1).

Our finding that, with disaccharide present in the intestinal lumen, glucose appears in the perfusate at a higher concentration than in the mucosal fluids is consistent with the view that, in the Amphibia we have examined, the disaccharides maltose and trehalose are absorbed as such and hydrolysis takes place in or on the intestinal epithelial cells. Similar results have been

found for maltose in the mammal³. If, as in the hamster, some of the disaccharidases are localized in the brush border of the absorbing cells⁷, the efficiency of capture of the products of hydrolysis by any hypothetical separate hexose transporting system must be high. One way of describing the phenomenon is to ascribe a vectorial component to the hydrolytic activity of the enzyme. In other words, for a disaccharidase in the brush border, the probability of escape of the products of hydrolysis in one direction, that is, into the cell, is higher than that of the escape in any other direction. If this is so, the vectorial effect is not only most evident on low disaccharide concentrations, but also depends on the presence of Na⁺ ions in the mucosal fluid, for we have found that the substitution of potassium or of lithium for the sodium in the mucosal fluid greatly reduced the transfer of glucose to the vascular fluid without affecting the total rate of disaccharide hydrolysis. Phloridzin (5×10^{-6} M) produced a similar effect. Such a vectorial effect could be due at least in part to the cyto-architectural arrangement of the disaccharidase molecules. For example, with the disaccharidase located in pores in the limiting membranes of the brush border of the absorbing cells the escape of glucose molecules from the inner end of the pore into the cell could be a rate-limiting step to the transfer of glucose at high rates of hydrolysis. A hypothesis of this sort raises the question as to what extent the ability of the mucosal cells to transfer single hexose units from the mucosal fluid into the vascular bed depends on the presence and orientation of oligosaccharidase molecules in the limiting membranes of the absorbing cells.

Protective Effect of Oestrogens against the Toxic Decomposition Products of Tribromoethanol

THE purpose of the present communication is to record that oestrogens have a protective effect against the toxic decomposition products of the anaesthetic tribromoethanol ('Avertin').

Tribromoethanol decomposes slowly on long-standing in the dark; but this process is much accelerated on exposure to the light. Stock solutions of tribromoethanol generally contain amylene hydrate, which acts as a solvent and also retards the breakdown process, but the manufacturers recommend that the stock solution should be tested before use for the presence of toxic decomposition products (dibromoacetaldehyde and hydrobromic acid) by assessing the colour changes when an aqueous solution of congo red indicator is added to the anaesthetic solution. When toxic breakdown products are present the indicator gives a blue coloration instead of the normal red.

In this laboratory we have used tribromoethanol extensively as a general anaesthetic for operative procedures in rabbits, guinea-pigs, rats and mice. We have used stock solutions of tribromoethanol which have been kept in the laboratory away from light for more than two years and they have shown no signs of decomposition or loss of potency, and the overall mortality due to the use of this anaesthetic has been negligible. The present observations were noted in an experiment where it was discovered that a stock solution of tribromoethanol purchased only one month beforehand and not tested by us for toxicity, contained lethal decomposition products.

The experiment was designed to investigate the effect of various doses of 17 β -oestradiol and diethylstilboestrol on the foreign body response. One hundred and twenty male white mice (T.O. Swiss strain) of 20–25 g body weight were used in the experiment. The mice were divided into ten groups each containing ten animals, and twenty animals were used as controls. Each of the test groups received oestrogen in the doses shown in Table 1 and each dose of oestrogen was administered orally by stomach tube in 0.1 ml. sterile distilled water². Immediately following the initial dose of oestrogen, the animals were taken to two separate operating rooms, six groups being taken to each. The mice were then anaesthetized by the intra-peritoneal injection of a 2.5 per cent aqueous solution of tribromoethanol given on the basis 0.01 ml. per g body weight. In one operating room, all the animals received anaesthetic freshly prepared from a stock solution of tribromoethanol which had been in use for the previous eighteen months. In the other operating room, the animals (groups marked * in Table 1) received anaesthetic freshly prepared from a stock solution of tribromoethanol which had been purchased one month beforehand. Bilateral subcutaneous implantation of sterile cotton wool dental pellets was then performed through a single dorsal mid-line incision so that a single pellet was implanted in each flank³. On recovery from the anaesthetic, the animals were returned to a thermostatically controlled heated animal house.

Twenty-four hours after operation it was discovered that a number of deaths had occurred in the groups which had received the three lower doses of 17 β -oestradiol (0.001, 0.01 and 0.1 mg); and the surviving animals in these groups, and also those in the group which had received 1.0 mg 17 β -oestradiol daily, showed signs of toxicity. The animals in all the other groups appeared to be well, and oestrogen treatment was administered to all the surviving mice. Forty-eight hours after operation, it was noted that further deaths had occurred in the groups which had received all except the highest dose of 17 β -oestradiol. It was also noted that the animals which had received the highest doses of 17 β -oestradiol and diethylstilboestrol showed signs of toxicity and two of the diethylstilboestrol-treated mice had died. The other diethylstilboestrol-treated groups and the controls were not affected, and oestrogen treatment of the survivors was carried out. Seventy-two hours after operation, it was noted that further deaths had occurred in all the groups which had received 17 β -oestradiol and also in the group which had received the highest dose of diethylstilboestrol. The other diethylstilboestrol-treated groups and the control animals had remained well.

Table 1. EFFECTS OF VARIOUS DOSES OF OESTROGEN ON SURVIVAL OF MICE AFTER INTRAPERITONEAL INJECTION OF TOXIC DECOMPOSITION PRODUCTS OF TRIBROMOETHANOL ('AVERTIN')

17 β -Oestradiol daily dose for 3 days (mg)	No. of animals in group	No. of survivors after operation			Diethylstilboestrol daily dose for 3 days (mg)	No. of animals in group	No. of survivors after operation		
		24 h	48 h	72 h			24 h	48 h	72 h
0.001	10*	5	1	0	0.001	10	10	10	10
0.01	10*	7	3	0	0.01	10	10	10	10
0.1	10*	9	5	2	0.1	10	10	10	10
1.0	10*	10	7	3	1.0	10	10	10	10
10.0	10*	10	10	5	10.0	10*	10	8	4
Untreated controls	10	10	10	10	Untreated controls	10	10	10	10

* Groups received toxic tribromoethanol.

At the conclusion of the experiment, the stock batches of tribromoethanol were tested for the presence of toxic decomposition products, and it was discovered that the batch used to anaesthetize the mice which had received all the doses of 17 β -oestradiol and the highest dose of diethylstilboestrol had undergone partial decomposition.

The observations recorded in this experiment show clearly that the administration of oestrogens has a marked protective effect against the lethal decomposition products of tribromoethanol (dibromoacetaldehyde and hydrobromic acid), and that the period of survival after administration of these toxins depends on the dose of oestrogen administered and lengthens with increasing doses of the oestrogen (Table 1).

Nicol and Zikry⁸ reported that oestradiol benzoate has a protective effect against the toxicity of trypan blue in guinea-pigs, and they attributed their findings to the stimulating effect of oestrogen on the reticulo-endothelial system which thus becomes more capable of taking up the dye and detoxicating it. It has also been reported that the reticulo-endothelial system plays an important part in protection against a variety of noxious agents⁹, and it seems possible that the protective influence of oestrogen against the toxic effects of dibromoacetaldehyde and hydrobromic acid may be the result of oestrogen-produced stimulation of the reticulo-endothelial system.

Aldosterone Secretion: Differences in Direct Effects of Rubidium and Potassium Perfusion into Dog Adrenals

MORE than eighty years ago, Ringer¹ observed that rubidium ions had effects on the frog's ventricles similar to those produced by potassium. Since then these two ions have been found to be very nearly interchangeable in a wide variety of biochemical and physiological processes².

The systems most extensively examined have been rat skeletal muscle³, rat acid-base balance⁴, dog renal excretions⁵ and the human erythrocyte⁶⁻⁸. In fact, Lahn⁸ has suggested that rubidium might be more effective than potassium in treating digitalis overdosage because rubidium is more resistant to the action of ouabain in depressing the entry of erythrocytes.

We now offer evidence that this mutual interchange of these two ions does not operate in one very important system; that is the adrenal cortex of dogs. Isolated adrenal glands of hypophysectomized dogs were prepared by the technique of Hilton *et al.*⁹. Aldosterone, hydro-

cortisone and corticosterone secretion rates were measured in the adrenal venous effluent during control collection periods, following perfusion of either potassium chloride or rubidium chloride, and after an injection of ACTH given at the end of each experiment. Potassium chloride was perfused in each experiment to achieve an arterial blood concentration of approximately 8 m.equiv./l. and RbCl was perfused to achieve a concentration of approximately 4 m.equiv./l. (Rb + K = 8 m.equiv./l.).

The effects of the potassium chloride infusion experiments are shown in Fig. 1. Potassium produced its expected stimulation of aldosterone secretion without effect on hydrocortisone or corticosterone secretion¹⁰. ACTH given at the end of each experiment caused stimulation of all three steroids. In contrast, as shown in Fig. 2, rubidium failed to alter aldosterone secretion. ACTH in these experiments again increased production of all three steroids.

These results were quite unexpected in view of the heretofore demonstrated interchangeability of these two ions in a wide variety of biological systems and the high penetrability of rubidium into cells. In experiments somewhat relevant to ours, Kunin *et al.*¹¹ and Tarail *et al.*¹² observed that electrocardiographic alterations in the dog were similar during infusions of potassium chloride, producing plasma potassium levels of 8 m.equiv./l., to those induced by RbCl producing plasma Rb levels of 4 m.equiv./l. (Rb + K = 8 m.equiv./l.). Also Glasser and Ellis¹³ found that rubidium could prevent the lipid depletion of the zona glomerulosa of rat adrenals otherwise produced by potassium deficiency and on this evidence suggested that rubidium could substitute for potassium in their system. However, aldosterone production was not measured in their experiments.

Lacking specific evidence for or against rubidium penetration into dog adrenal cortical cells, we cannot offer

Fig. 1. Stimulatory effect of potassium on aldosterone secretion in adrenals of hypophysectomized dogs. KCl was perfused at a concentration of 40 m.equiv./l. to achieve a final arterial concentration of approximately 8 m.equiv./l.

Fig. 2. Lack of effect of rubidium on aldosterone secretion in adrenals of hypophysectomized dogs. RbCl was perfused at a concentration of 40 m.equiv./l. to achieve a final arterial concentration of Rb+K=8 m.equiv./l.

any cogent explanation for our results and must conclude that, so far as aldosterone production in the dog adrenal is concerned, rubidium, at the concentration used, cannot be substituted for potassium. This would appear to be the first example of such a dichotomy between these two ions.

A New Property of the Early Receptor Potential of Rat Retina

In the dark-adapted eye, the amplitude of the early receptor potential (e.r.p.)¹ is linearly proportional to the number of molecules of rhodopsin bleached by a flash.² The second of a train of intense flashes evokes a smaller response because less rhodopsin is available.² However, with further stimulation, the e.r.p. reaches a steady voltage, about 10 per cent of the first response. This occurs even though each molecule of rhodopsin should, theoretically, have bleached many times over.³ The relationship established by Corie² breaks down after the second or third maximal flash. The reason for this is that

the flash causes regeneration of photopigment from stable product of bleaching, by a mechanism different from that analysed by Williams³. The regeneration can be demonstrated by exposing the eye to a series of intense flashes (Fig. 1) until the e.r.p. amplitude has reached stable lower level.

The eye is then exposed to continuous illumination from a tungsten source. Following this, the e.r.p. is again evoked with intense flashes. The first response is much smaller than the previous lower limit, but the subsequent e.r.p.s increase in amplitude. The experiment can be repeated several times.

The phenomenon shown in Fig. 1 is less pronounced if the retinal circulation is maintained. It is exaggerated if the tungsten illumination lasts for not longer than 5 min (Fig. 2A). It is greatly reduced if a filter, excluding wavelengths shorter than 460 nm, is placed in the light path. It is therefore likely that the flash photo-isomerizes a *trans*- to *cis*-retinal, thus initiating the synthesis of rhodopsin^{4,5}. The increase of e.r.p. amplitude is associated with an increase in amplitude of the electroretinogram. In separate experiments, it has been found that the change of amplitude corresponds to an increase in sensitivity of about 0.3 log units. The increase in rhodopsin concentration, predicted from the e.r.p. experiments, would account for this.

These experiments therefore support the theory of photo-regeneration. Our measurements of e.r.p. amplitudes show that the rhodopsin formed by this mechanism is partly bleached during the same flash. Since the regeneration time permits little diffusion, the retinal must still be bound to the opsin.

Fig. 2A shows that after adaptation to tungsten light the e.r.p. wave-form changes. At body temperature, a change that can be seen is that the initial, descending negative phase becomes more rapid. The e.r.p. can be slower and the negative phase abolished, by cooling^{6,7}. A positive potential is then revealed. If this experiment is performed with an eye which has been previously exposed to tungsten light, the wave-form is different from the already described^{6,7} (Fig. 2B). The positive e.r.p. is preceded by a negative deflexion. It is the latter which

Fig. 1. E.r.p.s of albino rats. Light shielded corneal wick electrode. Reference electrode in scalp. Pupil dilated. Stimulus, 50 J, 800 μ sec, xenon flash delivered by fibre optic bundle 1 cm in diam placed 1 mm from cornea, ensuring total uniform retinal illumination. Effective stimulus intensity, 2.8 quanta absorbed/rhodopsin mol./flash. Animal killed by overdose of urethane immediately prior to experiment. Calibration bars, 100 μ V, 2 msec. Stimulus delayed from start of trace. 30-sec interval between flashes. Ordinal number of flash indicated on left. E.r.p.s produced by sixteenth and thirty-first flash nearly equal in amplitude. Exposure to tungsten light, through same bundle, of intensity calculated to bleach total rhodopsin in about 5 min if no regeneration occurs. Subsequent to this exposure, the first test flash evokes a small e.r.p., but subsequent flashes evoke larger responses. The experiment can be repeated. Note rapid downward excursion of the trace after tungsten exposure. The initial positive potential is not visible, since the experiment was carried out near body temperature.

E.R.P. AFTER EXPOSURE TO TUNGSTEN LIGHT—XENON FLASH, WHITE

Fig. 2. E.R.P.s obtained after exposure to 5 min tungsten light. A, At body temperature, showing increasing responses to successive flashes. Note rapid negative deflexion. B, Responses obtained when excised eye placed on block of ice cooled by methanol-carbon-dioxide mixture. The eye was placed so that it did not become opaque (frozen). The later negative potential seen in 2A has disappeared. The first flash evokes a negative wave, previously undescribed, which is as rapid as the initial positive phase. In subsequent flashes, the negative potential decreases, while the positive potential grows. Calibration, 2 msec, and A, 100 μ V. B, 50 μ V.

causes the rapid downward swing at body temperature. The negative deflexion can only be seen after intense tungsten illumination. It cannot be seen if wave-lengths shorter than 460 nm are excluded. After the fourth flash it seems to have disappeared from the records. It may still be present, but obscured by the positive potential, which has grown. In some of our experiments, the positive response to the first flash is much smaller than in Fig. 2B, and it can then be seen that the time course of the negative response is much the same as that of the positive. It is distinct from the extra-retinal potential described by Brown⁸.

It therefore appears that the photolysis and synthesis of rhodopsin *in situ* are associated with potentials of opposite polarity. Both resist anoxia and low temperature, and have similar time courses. It is therefore possible that they are generated by the same reversible mechanism. This would imply that the responses have a closer relationship to the primary action of light than hitherto supposed⁷—either photoconduction in oriented molecules, or rotation of molecular dipoles.

PHARMACOLOGY

Inhibition of Conjugation by Anti-inflammatory Drugs

IBUFENAC (4-isobutyl-phenylacetic acid) has recently been introduced as an anti-inflammatory drug. In animals it possesses analgesic, anti-inflammatory and antipyretic properties¹. Thompson, Stephenson and Percy² found raised serum transaminase-levels in 12 of 36 patients treated with ibufenac. Five cases of jaundice have now been recorded in about 400 patients receiving ibufenac³.

Phenylbutazone, another anti-inflammatory drug, occasionally causes jaundice; 12 cases have been recorded⁴. The liver shows cholestatic and cytotoxic lesions⁵. Phenylbutazone has been given to patients with cirrhosis of the liver for 1-5 months without alteration of liver function tests⁵.

Using *in vitro* systems, we have examined the effect of ibufenac and phenylbutazone on conjugating mechanisms in the rat and rabbit liver. Bilirubin conjugation was determined in rat liver slices and rabbit liver homogenates by the method of Lafhe and Walker⁶. *o*-Aminophenol conjugation was determined in rat liver slices by the method of Levvy and Storey⁷ and in rabbit liver homogenates by the method of Stevenson and Dutton⁸.

The addition of ibufenac and phenylbutazone lowered the rates of conjugation of bilirubin and *o*-aminophenol by rat liver slices (Table 1). The transferase stage of conjugation was examined in rabbit liver homogenates incubated with ample uridine diphosphate glucuronic acid. Ibufenac and phenylbutazone reduced the rates of conjugation of bilirubin and *o*-aminophenol (Table 2).

Table 1. EFFECT OF ANTI-INFLAMMATORY DRUGS ON CONJUGATION IN RAT LIVER SLICES

Concn. (mM)	Rate of conjugation (μ g/g/h)			
	Ibufenac Bilirubin	<i>o</i> -Aminophenol	Phenylbutazone Bilirubin	<i>o</i> -Aminophenol
0	54	70	31	57
0.01	50	62	26	48
0.1	43	61	21	44
1.0	50	39	15	48
10.0	0	0	6	35

Table 2. EFFECT OF ANTI-INFLAMMATORY DRUGS ON CONJUGATION IN RABBIT LIVER HOMOGENATES

Concn. (mM)	Rate of conjugation (μ g/g/h)			
	Ibufenac Bilirubin	<i>o</i> -Aminophenol	Phenylbutazone Bilirubin	<i>o</i> -Aminophenol
0	248	300	190	243
0.01	248	273	120	252
0.1	216	182	0	245
1.0	220	50	0	226
10.0	0	14	0	194

Clinical trials of ibufenac have indicated that the drug is hepatotoxic; the reported incidence of jaundice is about 1 in 80 patients. The type of jaundice has not been defined, but liver biopsy in one case showed preservation of normal architecture with no evidence of bile stasis. The jaundice was mild and liver function rapidly returned to normal after withdrawal of ibufenac³. Rats given 100-250 mg/kg ibufenac orally for 27 weeks showed no evidence of liver damage, but doses of 625-1,000 mg/kg caused liver cell damage⁹. Ibufenac inhibits *o*-aminophenol and bilirubin conjugation in *in vitro* conjugating systems; the circulating concentration of ibufenac after normal dosage (2.4 g) is about 0.1 mM, so it is possible that glucuronyl transferase can be inhibited at therapeutic concentrations.

Phenylbutazone jaundice may be due to a direct action of the drug which is dose-dependent⁹. Cholestatic jaundice rarely results from phenylbutazone therapy; the jaundice has been associated with generalized allergic manifestations¹⁰. Therapeutic blood levels in man are 5-15 mg/100 ml; this is 0.15-0.5 mM, at which level inhibition of conjugation occurs *in vitro*.

Ibufenac and phenylbutazone uncouple oxidative phosphorylation¹¹; 50 per cent inhibition is produced by about 0.25 mM phenylbutazone and 1.0 mM ibufenac. Phenylbutazone inhibits a number of other enzymes, for example glutamic acid dehydrogenase¹² at similar concentrations.

Ibufenac and phenylbutazone cause jaundice, the former with probably greater frequency than the latter. The drugs inhibit conjugation at therapeutic concentrations in preparations *in vitro*.

Preferential Release of Adrenaline from the Adrenal Medulla by Muscarine and Pilocarpine

HISTOCHEMICAL examination of the adrenal medulla of several species, including the cat, has revealed two distinct types of chromaffin cell, one rich in adrenaline and the other rich in noradrenaline^{1,2}; and with appropriate physiological stimuli it is possible to release one or the other of these catecholamines more or less selectively³⁻⁵. Pharmacological investigations, on the other hand, have indicated that two types of 'acetylcholine receptor' are present in the cat's adrenal medulla. Attention was directed to this by Feldberg, Minz and Tsudzimura⁶, who found that both nicotine and pilocarpine had pressor effects when injected 'close-arterially' into the adrenal gland and that the effect of the former was blocked by excess nicotine while that of the latter was blocked by small doses of atropine. They were further able to demonstrate both nicotine-sensitive and atropine-sensitive components in the stimulant action of the splanchnic nerve on adrenal medullary secretion. Our purpose here is to present evidence suggesting that the two sets of phenomena are related: that, in the cat at least, pilocarpine and muscarine release adrenaline with little or no noradrenaline; while nicotine releases large amounts of noradrenaline as well as adrenaline.

Our experiments have been carried out on cat's adrenal glands acutely denervated and perfused *in situ* with Locke's solution following the method previously described⁷. Adrenaline and noradrenaline escaping from the adrenal vein were assayed by the fluorometric technique⁸. During the course of perfusion the gland was made to discharge catecholamines either by stimulating the splanchnic nerve for 20-30 sec with supramaximal shocks at 30/sec or by adding to the perfusion fluid various cholinomimetic drugs for the same length of time. These drugs fell into three groups: (a) acetylcholine (10^{-5} g/ml.); (b) muscarine and pilocarpine ($1-2 \times 10^{-4}$ g/ml.); (c) nicotine ($2 \times 10^{-6}-10^{-5}$ g/ml.).

Stimulation of the splanchnic nerve or the addition of acetylcholine or nicotine to the perfusion fluid caused the liberation of large amounts of both adrenaline and noradrenaline in each of many tests on different glands: the mean percentage of total catecholamines appearing as noradrenaline was 61 per cent with splanchnic nerve stimulation (24 tests), 58 per cent with ACh (10 tests) and 55 per cent with nicotine (7 tests). In contrast, pilocarpine and muscarine yielded quite different results: in 8 tests with pilocarpine, noradrenaline accounted for only 4 per cent of the total amines released and in 7 tests with muscarine, only 16 per cent. The contrasting effects of nicotine and pilocarpine in a single gland are shown in responses (N) and (P) of Fig. 1. Hexamethonium, in doses

Fig. 1. Secretion of catecholamines in response to pilocarpine (P), 10^{-4} g/ml., and to nicotine (N), 2×10^{-5} g/ml., given during perfusion with Locke's solution or Locke's solution with the addition of hexamethonium (C_6), 10^{-4} g/ml. or atropine 10^{-5} g/ml. Each agonist was introduced for 30 sec. The solid black columns indicate the secretion of adrenaline during perfusion with the agonists and the open columns indicate the corresponding secretion of noradrenaline.

that strongly inhibited the responses to nicotine, had little effect on the responses to pilocarpine or muscarine which, however, were readily blocked by atropine (Fig. 1). Feldberg, Minz and Tsudzimura⁶ noted in their experiments that large doses of nicotine failed to block completely the pressor effects of stimulating the splanchnic nerve, but that the residual response was reduced by atropine. We have obtained essentially similar results with hexamethonium, and have been able to show that the residual secretion persisting in the presence of large doses of hexamethonium (and blocked by atropine) is largely made up of adrenaline.

From the evidence provided by these various agonists and antagonists, it seems clear that there are two sets of acetylcholine receptors in the cat's adrenal medulla and that these are related to the preferential release of the two catecholamine hormones: the receptors activated by pilocarpine and muscarine appear to be associated principally with the release of adrenaline, while those activated by nicotine are involved in the release of both adrenaline and noradrenaline. A simple interpretation of the effect of muscarine and pilocarpine would be that the receptors they activate are mainly on cells containing only adrenaline; while the fact that nicotine releases adrenaline and noradrenaline would suggest either that 'nicotine receptors' are present on both adrenaline and noradrenaline-containing cells or, alternatively, that nicotine is capable of activating the same receptors that respond to muscarine.

It is remarkable that so little attention has been paid to the presence in the adrenal medulla of receptors responding to muscarine and related drugs to which the work of Feldberg *et al.*⁶ so clearly pointed. Time and again cholinomimetic substances have been screened for adrenal medullary stimulating activity in animals given atropine. Obviously adrenal medullary stimulants of the muscarine type are missed in such tests. Confusion has arisen from the common pharmacological practice of equating 'nicotinic sites' of drug action (in the gross anatomical sense) with 'nicotine receptors' at the cellular level. The adrenal medulla, where nicotine is certainly an outstandingly effective agent, numbers among the familiar 'nicotinic sites', and there has been a tendency to assume an absence of muscarine receptors there. This assumption is certainly unfounded in the cat where muscarine receptors appear to be intimately related to the secretion of adrenaline. Feldberg *et al.*⁶ report that they performed only

a few experiments with muscarine, and that, because of its depressant effects on heart and general circulation, it was difficult to be certain of its action on the adrenal medulla. Nevertheless they state that they did record, in several instances, an undoubted, though weak, pressor effect abolished by atropine. They do not mention the doses they employed. In our own experiments where we have used *d*-l-muscarine iodine we have found that muscarine is capable of evoking very strong secretory responses; for example, in each of four tests a brief exposure (20 sec) to muscarine in a concentration of 10^{-4} g/ml. raised catecholamine output during this period from resting values under $0.05 \mu\text{g}$ to more than $9 \mu\text{g}/\text{min}$.

The fact that atropine is a highly effective blocker of the muscarine receptors may prove to be of considerable heuristic value in the physiological analysis of their function in the body's economy. It will, of course, be necessary to examine other species to determine the general significance of the muscarine receptors and their relation to the preferential release of adrenaline.

It is pertinent that receptors activated by muscarine-like drugs and blocked by low doses of atropine also occur in sympathetic ganglion cells⁹ which are developmental homologues of the medullary chromaffin cells. The sympathetic ganglia have also been most commonly considered as 'nicotinic sites'. In the ganglia, however, the functional distinction between muscarine and nicotine receptors is not so evident as it is in the adrenal.

HAEMATOLOGY

Quantitative Determination of Haemoglobin A_2 by Acrylamide-gel Electrophoresis

A PROBLEM of great interest to the clinician is the diagnosis of thalassaemia trait. An objective and specific test for detection of this disease was first offered by Kunkel *et al.*^{1,2} who, using starch block electrophoresis, found that in cases of thalassaemia trait the A_2 haemoglobin was characteristically elevated. This fraction has been extensively investigated by electrophoresis using paper³, starch block^{4,5}, starch gel⁶, cellulose acetate⁷, and acrylamide gel⁸ as the supporting media. Both starch block and starch gel electrophoresis are widely used to-day for haemoglobin analysis but are difficult to standardize and require a great deal of 'laboratory technique'. Acrylamide gel is superior to starch in that it is easier to work with, is more reproducible, is faster and the fractions can be quantitated by direct densitometry^{9,10}.

The work recorded here was undertaken to compare quantitatively starch-block and acrylamide-gel electrophoresis and to establish the normal ranges of haemoglobin A_2 as determined by acrylamide gel electrophoresis.

Blood specimens collected with any standard anticoagulant were prepared as described by Pearson and McFarland⁴. In lieu of ultracentrifugation satisfactory clear haemolysates may be obtained by filtering after routine centrifugation through *S* and *S* No. 289 analytical filter pulp. Prior to electrophoresis the haemolysates were diluted 1:1 with the working buffer solution.

The working buffer solution was the *tris*-borate-EDTA buffer described by Peacock¹¹. Electrophoresis was performed using a vertical cylindrical cell (Arden Instruments, Inc., Rockville, Md., U.S.A.) designed by us¹². After electrophoresis for 1 h at 300 V the gel patterns were scanned unstained by a recording densitometer equipped with a 500-m μ interference filter¹⁰. The area below the curves is integrated automatically and the percentage distribution of the fractions is calculated in the usual manner.

A typical separation of normal and abnormal haemoglobins by acrylamide-gel electrophoresis and a composite densitometer scan of the various components is shown in Fig. 1. Blood specimens from apparently healthy donors were analysed quantitatively by the starch block technique of Pearson and McFarland⁴. Thirty-six specimens with the A_2 haemoglobin in Pearson's normal range (1.5–3.1 per cent) were then separated on acrylamide gel and the fractions quantitated by direct densitometry. The mean value of the A_2 haemoglobin by this method was 2.9 per cent; the standard deviation was 1.5 and the normal range (mean \pm S.D.) was 1.4–4.4 per cent.

Several investigators have reported the normal range of the A_2 haemoglobin content obtained by various methods. Aksoy *et al.*³, using paper electrophoresis, and Pearson and McFarland⁴, using the starch-block technique, reported the normal range to be 2.6–3.5 per cent and 1.5–3.1 per cent respectively. Goldberg and Ross⁶, using starch-gel electrophoresis, found the normal range to be 2.4–4.5 per cent. Rozman *et al.*⁷ obtained a normal range of 2.4–4.1 per cent for A_2 using cellulose acetate electrophoresis. Nakamichi and Raymond⁸, using acrylamide-gel electrophoresis, found the normal range to be 0.5–5.0 per cent. In work recorded here the normal range was 1.4–4.4 per cent. From an analysis of the foregoing it is apparent that the upper range of the A_2 haemoglobin determined

Fig. 1. Normal and abnormal haemoglobins separated by acrylamide gel electrophoresis with a composite densitometric scan

by acrylamide-gel electrophoresis is generally higher than that obtained by other methods.

IMMUNOLOGY

Time-course Studies on Antibody Response in Thymectomized and Sham-thymectomized Mice

THE observation that neonatal thymectomy is associated with immunological defects¹⁻⁴ has stimulated new interest in the thymus as an organ important in the production of immunity. Antibody response and reaction to homologous skin grafts are the usual criteria of the immune capacity of the animal. Whether or not any particular, completely thymectomized animal shows immunological defects depends on the species and strain of the animal and the age of the animal when thymectomized. More recently⁵⁻⁷ thymectomized animals of the same strain have been shown to have decreased responsiveness to some antigens and not to others. In all these investigations, one or two time-intervals between injection of antigen and sampling for antibody activity were chosen. This communication deals with the haemolysin response to sheep red blood cells at various times after immunization. A delay in antibody formation in the thymectomized mice is demonstrated, and the danger inherent in the use of a single time interval between injection and serum collection is pointed out.

Swiss albino mice, inbred in this laboratory for 25 generations, were thymectomized or sham-thymectomized within 24 h of birth according to the method of Miller^{8,9}. Only the occasional mouse showed signs of wasting and only normal-appearing mice without abscesses were used in this investigation. Sheep red blood cells in Alsevers solution (Baltimore Biological Laboratory—BBL) were washed four times in Krebs-Ringer phosphate (KRP) solution at pH 7.4. At 6 weeks of age, each mouse received by intraperitoneal injection 0.1 ml. of a 10 per cent suspension of red blood cells for immunization. Blood was obtained from cut tails. Serum was inactivated, then serially diluted in 'Microtiter' plates (Cooke Engineering Co., Arlington, Va., U.S.A.)¹⁰ and guinea-pig complement (BBL) added. The plates were incubated at 37° C for 30 min; sheep red blood cells were added and incubated for 2 h at 37° C. The plates were then stored for about 20 h at 30° C. A dilution giving approximately half haemolysis was considered positive. All the titres are expressed as the negative logarithm to the base 2 of the dilution.

Fig. 1 shows the haemolysin response during the first 20 days following immunization with the sheep red blood cells. Sham-thymectomized animals displayed a two-

peaked response with the first peak occurring at 4 days, and the second peak occurring at 12–14 days. Thymectomized animals had a single-peaked response. The peak of this response occurred at 10 days and the titre reached one-sixth to one-eighth that of the sham-operated animal at 4 days. In the thymectomized animal there was no detectable haemolysin activity on or before 6 days.

By ultracentrifugation in a 10–40 per cent linear sucrose gradient in KRP solution the 19S and 7S classes of antibody could be separated¹¹. The first peak in the sham-thymectomized animal's response was found to be of the 19S class, and the second of the 7S class. In the thymectomized animals the antibody was of the 19S class at the peak, the 7S antibody appearing later.

It seems unlikely that the delayed response in thymectomized animals can be related directly to the lack of competent cells, since this lack, without any complicating compensating mechanisms, should lead to a decrease in the strength of response without alteration of the time relationships of the response. To produce a delay, competent cells stimulated by the sheep red blood cells must reach the stage of producing antibody at a later time. On the other hand, the decreased haemolysin titres observed in thymectomized mice can best be explained on the basis of a lack of competent cells or on a more rapid removal of circulating antibody⁶.

Keeping in mind the various responses to different antigens observed using a single time interval after immunization, it is worth looking at some arbitrary times in the present haemolysin response. If 6 days had been chosen, no haemolysin response in the thymectomized animals and a considerable response in the sham-thymectomized animals would have been observed. If 9 days had been chosen, no difference in the total haemolysin response between thymectomized and sham-thymectomized animals would have been detected. If later arbitrary times had been chosen, a decreased haemolysin response would have been observed in the thymectomized mice. Therefore, as a distinct possibility, the varying response in the same strain to different antigens observed by others could be explained at least in part on the time chosen for the antibody testing, or, if the time chosen for investigating the various antigens was kept constant⁵, on the time-course of the antibody response to that particular antigen. Using similar reasoning, the differing effects of thymectomy on primary and secondary response¹² could be due to the fact that the antibody activity of the thymectomized animals may have been sampled near the peak times for one response but not for the other. One of the more prominent sources of variation in the effect of neonatal thymectomy on antibody response is strain differences. While it seems unlikely that the

Fig. 1. The negative logarithm to the base 2 of the average haemolysin titre at various times after immunization is shown for both thymectomized (▲) and sham-thymectomized (△) animals. Each point represents at least 6 serum haemolysin determinations

degree of responsiveness observed in various strains would be altered to any great extent by using different time intervals between injection of the antigen and collection of the antibody-containing sera, the possibility should not be eliminated without investigation.

Thymectomized animals of a strain that has not shown an antibody response at a particular time may not respond at any time, or may have an antibody response at some later time. It may be important to distinguish between these possibilities when looking at the mode of action of an agent which protects a thymectomized animal against the usual immunological defects characteristic of that strain. Is the agent allowing the development of an immune response normally absent in the thymectomized animals, or is it merely shifting the response present in the thymectomized animals so that the response can now be detected at the particular time interval chosen? To answer this and related questions, one must determine antibody responses at various times after immunization.

I thank Prof. J. A. McCarter for his advice.

Inactivation of T-2 Bacteriophage by Sensitized Leucocytes *in vitro*

ALTHOUGH *in vitro* investigations of the primary¹ and secondary^{2,3} phases of the immune response have been reported, few investigators have used blood as a source of immunologically competent cells⁴⁻⁶. The use of blood instead of lymphoid organs as a source of cells enables the investigator to obtain multiple samples of a homogeneous cell population. This communication reports a preliminary approach to an immunological investigative system consisting of sensitized rabbit blood leucocytes and T-2 bacteriophage, a particulate antigen that can be assayed by a procedure which is relatively simple, sensitive and quantitative.

T-2 bacteriophage is assayed by the soft agar method described by M. H. Adams⁷. *E. coli* (strain B 295) is used to prepare bacteriophage stock and serves as the susceptible bacterium in the plaque assay. This organism is maintained on agar slants (stock) and in 'L. C.' broth⁸. The assay is carried out by overlaying 'L. C.' agar with 3.5 ml. of soft agar (0.5 per cent agar in water) in which a 0.1-ml. sample of T-2 phage has been mixed with 0.1 ml. of *E. coli*. The bacteria, prepared daily from an overnight culture, are held in early log phase (O.D. 60-90 Klett-Summerson units, red filter) by maintenance at room temperature. Phage dilutions, producing 20-40 plaques per dish, are plated in triplicate and the results are averaged.

T-2 bacteriophage is prepared according to a modified method described by M. H. Adams⁷. Phage at a total concentration of 5×10^7 P.F.U. (plaque forming units) is added to 20 ml. of *E. coli* in log phase, and the mixture incubated for 6 h. The cells are lysed by adding 0.5 ml. chloroform. Bacterial debris is cleared by centrifugation at 3,000g for 30 min. The virus is pelleted by centrifugation at 27,000g for 2 h. The phage is resuspended in medium 56 (ref. 9). This yields a titre of about 1×10^{11} P.F.U. per ml.

Larger amounts of phage are prepared by proportionately increasing the volume of reagents added. To avoid the time-consuming high-speed centrifugation, phage is precipitated by adjusting the pH of the supernatant of the low-speed centrifugation to pH 4.2 with concentrated HCl. The virus is then pelleted by centrifugation at 9,750g for 15 min. It is resuspended as outlined above.

Two intraperitoneal injections of 5×10^{10} P.F.U. of phage were given to male New Zealand rabbits twice a week for three weeks. Ten days later they were given 1×10^{11} P.F.U. of phage subcutaneously, and this dose was repeated twice at six-day intervals. The first blood sample was drawn two weeks after the last injection; the last sample was drawn a month later.

Blood was obtained by cardiac puncture. Heparin (Mann Research Labs.) was used to prevent coagulation (4×10^{-2} mg/ml. of blood). The blood was mixed with a 3.5 per cent gelatine solution (Fisher USP) in a 3:1 ratio (15 ml. of blood to 5 ml. of gelatin) and allowed to stand for about 20 min at 37° C (ref. 10). The supernate containing the leucocytes was removed and diluted to 70 per cent with CM (culture medium; Eagle's medium with 10 per cent foetal bovine serum)¹¹. The cells were centrifuged into a loose button at 1,000 r.p.m. for 6.5 min in a clinical centrifuge. The contaminating red cells were removed by resuspending the cells in 0.85 per cent NH_4Cl for 5 min¹². The leucocytes were then washed three times in CM.

The leucocytes were counted by a Coulter 'Model B' counter using a 50- μ pore, coupled to a size distribution write-out¹³. A dye exclusion test using Erythrosin B demonstrated a 98 per cent viability¹⁴.

Suspensions of leucocytes and phage in 4 or 5 ml. of CM were incubated at 37° C in 1 oz. stoppered prescription bottles filled with 5 per cent CO_2 in air. The degree of neutralization was determined by assaying the P.F.U. in the medium after centrifuging the cells out of suspension.

The results of several experiments employing varying phage and leucocyte concentrations are shown in Table 1. The rapid and steady decline in the number of P.F.U. is

Table 2. NUMBER OF INFECTIVE PHAGE PARTICLES REMAINING AFTER INCUBATION WITH NORMAL (UNSENSITIZED) LEUCOCYTES OR WITH NO CELLS PRESENT

Experiment	Animal	Cell concentration/ml.	P.F.U. added/ml.	Days					
				0	1	2	3	4	5
5	O	3.62×10^6	2,500	2,200	2,600	1,700	2,650	1,900	3,000
6		no cells	2,500	2,500	2,100	1,550	2,150	1,200	2,000
7	L	1.96×10^6	2,000	2,250	1,300	1,250	1,430	1,100	1,000
8		no cells	2,000	1,850	1,700	1,700	600	1,200	1,000

graphically demonstrated in Fig. 1, which is a plot of experiment 3. The discrepancy between the number of P.F.U. added and the number present on day 0 is due to the neutralization of T-2 phage by residual immune serum and a slight shift in plating characteristics when the virus is suspended in CM.

When similar cultures of phage and leucocytes from an unsensitized animal were prepared and assayed (expt. 5), the number of P.F.U. did not decline steadily. Comparable results were observed when phage was incubated alone in CM (expt. 6; Table 2). The results of these experiments are plotted in Fig. 2 for comparison with Fig. 1.

Fig. 2. P.F.U./ml. present in culture after incubation with unsensitized leucocytes or no cells present (experiments 5 and 6). ●, Normal leucocytes; ○, tissue culture media

The titre of the control cultures (phage incubated with unsensitized leucocytes or no leucocytes) did not remain constant. A kinetic study of this problem has been carried out in another laboratory and it appears that the original virus sample contained two populations of T-2 phage, one of which has a tendency to aggregate and dissociate¹⁵. This factor was not of critical importance in the present investigation, in which only the steady decline in P.F.U. was investigated.

Immunofluorescent studies have suggested that antibody production *in vitro* is most active on the third or fourth day of incubation^{4,16}. Plaque assay analysis³ and localized haemolysis techniques⁶ have detected specific

antibody formation after 24-h incubation, the latter method demonstrating peak synthesis on the fourth day. Our work confirms antibody production early in the incubation period, but suggests that somewhat different kinetics are involved. Whether the specific inactivation of phage in our system is due to antibody synthesis *in vitro*, release of preformed antibody, and/or phagocytosis is a subject for continued research.

Electrophoretic Mobility of an Immune Globulin from Rainbow Trout Serum

CONSIDERABLE interest has been focused recently on the comparative aspects of the immune response in vertebrates. A sound knowledge of the development of the immune response at various phylogenetic stages in existing vertebrates may clarify the evolution of the various aspects of vertebrate immunity through its highest development in mammals and birds, and provide a better understanding of the mechanisms involved. This communication reports findings concerning the immunoelectrophoretic mobility of an immunologically active fraction of serum from a teleost fish, rainbow trout (*Salmo gairdneri*).

Rainbow trout were immunized by injecting washed rabbit erythrocyte suspensions intracoelomically into a number of fish maintained at a constant water temperature of 15° C. The antisera of highest titre from two of these fish were selected for preparing anti-trout immune globulin sera. Both of these trout anti-rabbit erythrocyte sera were obtained from bleedings made more than 2 months after initial stimulation. The anti-trout immune globulin sera were prepared by injecting three rabbits intraperitoneally three times a week for 2 weeks with saline suspensions of rabbit erythrocytes coated with trout globulin. The rabbit erythrocytes were sensitized by incubation in 1:10 saline dilutions of the trout anti-rabbit erythrocyte sera followed by three washings in 10 volumes of 1 per cent saline solution. One-ml. aliquots of freshly prepared 25 per cent suspensions of sensitized rabbit erythrocytes in saline were used as inocula.

Two other antisera were used in this study. One, a rabbit anti-human serum reagent furnished by Dr. R. S. Weiser, was used to compare electrophoretic migrations of rainbow trout and human serum components. The other, prepared in rabbits from injections of sockeye salmon (*Oncorhynchus nerka*) red cell haemolysate preparations, was used for comparison of electrophoretic mobilities and immunological specificities with salmon globulins previously studied by immunoelectrophoresis¹.

The anti-trout immune globulin reagents were initially screened by the double-diffusion precipitation technique of Ouchterlony as modified by Ridgway *et al.*² and were found to contain precipitins. That these were immune and not normal precipitins was confirmed by similar tests comparing pre-immunization sera with post-immunization sera. Immunoelectrophoretic tests were made as described by Krauel and Ridgway¹.

Fig. 1 represents an immunoelectrophoretic slide comparing components in normal rainbow trout serum detected by the anti-trout immune globulin and anti-sockeye salmon haemolysate reagents with components of human serum detected with antihuman serum. When antisera from the other two rabbits were tested against normal trout serum, results were obtained comparable with those of the anti-trout immune globulin reagent used in Fig. 1. These arcs are asymmetrical, indicating that trout immune globulin is heterogeneous with respect to electrophoretic mobility and possibly to molecular size. The anti-haemolysate reagent detected two components in rainbow trout serum of distinct electrophoretic mobilities, the faster component having the same mobility as the component detected by the anti-trout immune globulin reagent. It is of interest to observe in the latter case that, while the mobilities are identical, the two components are not immunologically cross-reactive. Using the human serum-anti-human serum lines as a standard, the two faster components of the rainbow trout serum migrate as beta globulins while the slower component detected by the anti-haemolysate reagent has the mobility of a fast gamma or slow beta globulin.

Neither the beta nor the gamma globulin components of the rainbow trout serum which were detected by the anti-haemolysate reagent have been associated with immunological activity. These components have not been found in all sockeye salmon sera¹, while the component detected by the anti-trout immune globulin reagent has been present in sera of all trout or salmon tested.

Fairley and Harris³ incubated rabbit erythrocytes in human sera containing normal agglutinins for rabbit red cells. They subsequently found that these sensitized red cells were agglutinated by antisera against complement as well as by antisera against human antibody. In our studies with anti-trout immune globulin sera, the possibility cannot be excluded that the precipitins may represent trout complement-rabbit antibody precipitation as well as trout antibody-rabbit antibody precipitation.

No immunologically active globulin with true gamma 2 mobility was detected by this procedure. This accords with the finding of little or no gamma 2 globulin reported by Deutsch and McShan⁴ and Engle *et al.*⁵ for several species of teleosts; by Clem and Sigel⁶ for the margate (*Haemulon album*); and by Post⁷, who partially purified rainbow trout anti-bacterial antibody and studied its mobility by paper electrophoresis. However, Uhr *et al.*⁸ have reported significant levels of gamma 2 globulin in anti-phage sera from the goldfish (*Carassius auratus*) 2-4 weeks after immunization, and much increased levels of gamma 2 globulin two months after immunization. Also, Papermaster *et al.*⁹ found 'multiple gamma bands' by starch-gel electrophoresis and immunoelectrophoresis in the teleosts they studied. The variations in globulin mobilities reported suggest that either the various experimental approaches result in different responses, or that different species of teleost fish cannot be considered to be identical with respect to the molecular species of globulins with antibody activity.

PATHOLOGY

Lactic Dehydrogenase Isoenzymes in Muscle from Patients with Duchenne Muscular Dystrophy

THE enzyme lactic dehydrogenase (LDH) can be separated into five different isoenzymes, each composed of a tetramer of one or both of two distinct polypeptides^{1,2}. Isoenzymes 1 and 5 are composed solely of one of these two polypeptides, and isoenzymes 2, 3 and 4 consist of combinations of the two polypeptides. The proportions of the five isoenzymes vary from tissue to tissue, during development and with certain other environmental factors^{3,4}. In skeletal muscle one such factor is the amount of muscle activity⁴.

Several reports⁵⁻⁹ have indicated that the proportion of LDH 5 in muscle from patients with Duchenne's dystrophy was significantly reduced. Two of these authors^{6,7} were

Fig. 1. Immunoelectrophoretic mobilities of globulin components of normal rainbow trout serum compared with components of human serum. A, Rabbit anti-sockeye salmon red cell haemolysate antiserum; B, normal rainbow trout serum; C, rabbit anti-trout immune globulin antiserum; D, human serum; E, rabbit anti-human serum antiserum.

unable to detect any LDH 5 activity. These findings suggested a plausible biochemical cause for Duchenne's dystrophy, namely the incorrect construction of the polypeptide that solely constitutes LDH 5. The other polypeptide of LDH being normal would allow for some activity in the remaining four tetrameres, assuming that the inactive polypeptide could remain structurally competent to bind the functional polypeptide. Furthermore, the fact that LDH 5 functions under anaerobic conditions more effectively than LDH 1 might contribute a physiological explanation for muscle weakness or premature degeneration in a fibre lacking the sub-units of LDH 5. Therefore, it seemed important to investigate in further detail LDH activity from muscle biopsies obtained from dystrophic patients. Besides starch electrophoretic separation of the LDH isoenzymes from biopsy and tissue culture the results of pyruvic inhibition and histochemical determinations of LDH are reported briefly in this communication.

The three subjects of the investigation were boys with the onset of progressive muscular weakness at approximately five years of age. Although none had other affected family members, all had pseudohypertrophy of muscles and the typical biopsy and serum findings associated with Duchenne's dystrophy. Patients 1 and 2 were eight years of age and were only mildly affected. Patient 3 was fourteen years old and confined to a wheel-chair. Investigations were carried out on biopsies from deltoid muscle.

The fresh muscle was homogenized in 0.2 tris buffer (pH 8.3) and the supernatant LDH activity was measured by the method of Bergmeyer *et al.*¹⁰. The isoenzymes were separated by starch-gel electrophoresis (5 V/cm)¹¹ and stained for LDH activity¹². The total activity added to the slots was made equal through appropriate dilution of the supernatants. Cells derived from tissue culture of the biopsy were washed and homogenized before addition to the starch-gel slots. The frozen tissue was sectioned at 5 μ and 8 μ thicknesses and stained, together with appropriate controls, for LDH activity by the method of Thomas and Pearse¹³.

Although LDH 5 was clearly present in all three (Fig. 1), the first two patients showed some decrease in its relative proportion. The third showed no decrease. The isoenzyme patterns obtained from the cells tissue-cultured from the muscles predominantly showed LDH 5, as did the controls. An unexpected observation was that in patient 3 a neurogenic type of atrophy was found in the deltoid region, although the previous muscle biopsy from the calf was compatible with progressive muscular dystrophy. The

Table 1. ENZYME ACTIVITIES IN SERUM AND MUSCLE

* Wroblewski units.

total LDH activity in the muscle from the dystrophic boy was less than the control (Table 1). The percentage of LDH activity measured using 10^{-3} M pyruvate was reduced but not to the extent of heart muscle, which contained practically no LDH 5 (Table 1). The histochemical stains for LDH revealed no differences in amount or intracellular location of precipitate.

The isoenzyme patterns showing LDH 5 in these three particular patients presumably affected by the clinical syndrome of Duchenne's dystrophy differ from those reported by Emery, who found no LDH 5. In view of Zondag's work¹⁴, which shows that LDH 5 is more labile when frozen, it is possible that Emery in storing his samples at -15° C destroyed LDH 5. In confirmation of Zondag's findings, loss of LDH 5 activity was found after freezing homogenates obtained from both normal and dystrophic muscle; however, partial preservation was accomplished by adding nicotinamide adenine dinucleotide. The present observations tend to suggest that the small reduction in LDH 5 isoenzyme is secondary to physiological changes in the muscle rather than a primary biochemical change in progressive muscular dystrophy.

RADIOBIOLOGY

A Reduced Oxygen Enhancement Ratio for X-ray Survival of HeLa Cells *in vitro*, after Treatment with 'Methotrexate'

THE importance of anoxic cells within human tumours as a potential cause of failure when these tumours are treated by X- or γ -ray therapy has been realized for more than ten years^{1,2}. Clinical attempts have been made

render all tumour cells well-oxygenated by irradiating patients while they are breathing pure oxygen under increased pressure in a tank, and radiations of higher ionization density such as some fast neutrons, which are relatively independent in their effects of the presence or absence of oxygen, have passed the stage of preliminary trials^{3,4}. A similar clinical result, however, might be obtained by using a chemical modifier of radiation effects which produced greater potentiation of X-ray cell-killing under anoxic conditions than under well-oxygenated conditions⁵.

As part of a continuing investigation of the mechanism of cellular recovery from X-ray damage⁶, the reproductive survival of HeLa S-3_{oxf} cells was determined by clonal growth after single and fractionated X-irradiations delivered under oxygenated or anoxic conditions. Growth media and criteria for reproductive survival were as previously described⁷; all irradiations were carried out 8–24 h after the cells were plated in Falcon TC Petri dishes so that they were well attached to the plastic surface at the time of irradiation. Oxygenated conditions are defined as a humidified mixture of 5 per cent carbon dioxide in air flowing over the medium at the time of irradiation; anoxic conditions were produced by gassing the Petri dishes in a brass pressure tank for 6 h with humidified 5 per cent carbon dioxide in white spot purity nitrogen (British Oxygen Co., Ltd.) at a flow rate of 50 ml./min. The oxygen contamination of the effluent gas was measured by a Hersch cell and was less than 15 parts per million. (These measurements were kindly performed by Dr. E. J. Hall and Mr. J. S. Bedford.) Irradiation with 250 kVp X-rays (half-value layer = 1.3 mm copper) was by a simultaneous, parallel-opposed field technique (focal-skin distance = 50 cm) at a dose-rate of 43 rad/min measured under aerated conditions by a ferrous sulphate dosimeter inside the brass pressure tank. In additional experiments with and without 'Methotrexate', cells were irradiated under oxygenated conditions with 90 kVp X-rays (half-value layer = 1.1 mm aluminium) at a dose-rate of 169 rad/min. This latter technique produced dose-response curves which were indistinguishable from those produced by irradiating the cells under oxygenated conditions inside the brass pressure tank with 250 kVp X-rays.

'Methotrexate' (4-amino-10-methylpteroylglutamic acid, Lederle) was added to the growth medium at the time of plating, removed 24 h later by aspiration, and replaced with identical medium without the drug, after washing the plates once with complete growth medium without serum. This treatment sensitized the cells to X-irradiation even at concentrations of the drug which did not themselves produce any cell-killing, as is shown in Fig. 1. Higher concentrations of 'Methotrexate' present in the medium for only 24 h killed a proportion of the cells outright, although the growth medium contained folic acid in a concentration of 0.01 $\mu\text{g/ml}$. Those cells not synthesizing DNA during the 24-h period while the 'Methotrexate' was present in the medium escaped its effect regardless of the concentration of the drug in the medium (Fig. 2); this is similar to earlier observations of effects of the anti-metabolite 5-fluorouracil on survival of HeLa cells *in vitro*⁷.

At a drug concentration of 0.3 $\mu\text{g/ml}/24\text{ h}$, the X-ray dose-response curve for 'Methotrexate' survivors showed a significantly reduced oxygen enhancement ratio (OER), as shown in Fig. 3. If this observation is confirmed in other cell lines and in tumours *in vivo*, it would predict a therapeutic 'gain factor'⁸ of 1.56 over X-irradiation without the drug present, for killing anoxic tumour cells. Even if a major effect of 'Methotrexate' is simply to partially synchronize the cell population by selecting as survivors only those cells which have not yet begun DNA synthesis⁹, the fact that the subsequent survival after X-irradiation is less sensitive to the presence or absence of oxygen suggests that this drug may be useful in com-

bination with radiotherapy. One would expect, however, that the total X-ray dose administered would have to be suitably reduced both because the effect of single X-ray doses is potentiated by 'Methotrexate', and because HeLa cells show a markedly decreased ability for recovery between fractionated irradiations in the presence of 'Methotrexate'⁶ which would magnify the effects of a fractionated course of irradiation as compared with a similar course without the drug present when normal intracellular recovery could take place. This effect of 'Methotrexate' on recovery is likely to explain the recent finding of Condit *et al.*¹⁰, that the combination of intravenous administration of 'Methotrexate' with radiotherapy produced unacceptable normal tissue response if protracted treatment schedules were used, but no significant toxicity if short, intensive radiation courses were given.

It is hoped that the laboratory finding of a reduced oxygen enhancement ratio in the X-ray dose-response of a strain of human cells treated previously with 'Methotrexate', combined with the favourable early clinical

Fig. 1. X-ray dose-response, HeLa S-3_{oxf}

Fig. 2. Reproductive survival of HeLa S-3_{oxf} cells after 24-h exposure to 'Methotrexate'

Fig 3. X-ray dose-response, HeLa S-3 cells under anoxic or oxygenated conditions. Survival curve parameters are as follows (a) no 'Methotrexate', $n=2.0$, D_0 anoxic = 595 rads, D_0 oxygenated = 210 rads, (b) 'Methotrexate' $0.3 \mu\text{g/ml/24 h}$, $n=1.25$, D_0 anoxic = 200 rads, D_0 oxygenated = 110 rads

evaluation of this drug in conjunction with radiotherapy^{10,11}, may lead to larger-scale, systematic and controlled clinical evaluation.

Effects of Dietary Levels of Phosphorus and Calcium on the Comparative Behaviour of Strontium and Calcium

THE body burden of radioactive strontium to be attained in the population depends directly, among other factors, on the comparative metabolic behaviour of ingested strontium and calcium¹. Early work demonstrated a degree of constancy in the relative behaviour of the two elements that made such an approach useful for approximate estimates of radiation dosages to be expected from given intakes of calcium and radioactive strontium. An important practical implication was that if the relative behaviour were constant, then the body burden of radio-

active strontium to be developed could be proportional, reduced by dietary supplementation with uncontaminated calcium². More detailed investigation, however, shows that the relative behaviour of these two alkaline earths did vary under certain conditions³⁻⁵. Therefore the work recorded here was done in growing rats to investigate systematically two important variables which were shown to affect the relative absorption and retention of calcium and strontium; namely, the dietary levels of calcium and phosphorus.

The terminology is that of the 'observed ratio' where $OR_{\text{bone/diet}} = \frac{\text{Sr/Ca of bone}}{\text{Sr/Ca of diet}}$ and values of OR were determined by short-term double tracer investigations. The details of this procedure have been described previously⁶. The rats were of a highly inbred albino strain and were 8-9 weeks of age at the time of the experiment. After weaning they were raised on a stock diet containing 1.2 per cent calcium and 0.8 per cent phosphorus. At the start of the experimental period the animals were placed on the given experimental diet; 2 days later they receive tracer levels of ⁸⁵Sr and ⁴⁵Ca (or ⁴⁷Ca) incorporated in the drinking water for a 2-day period. After the end of the radionuclide application the animals were maintained on the experimental diet for another 2 days and then killed for tissue analysis. Thus, the rats were on the experimental diet for a total of 6 days, receiving the tracer strontium and calcium during the 3rd and 4th days. The skeletons were dissected from the soft tissue and ashed at 800° for 18 h. The ashed skeletons were dissolved in warm hydrochloric acid and the solution made to volume for the radioactive assays.

The effects of calcium and phosphorus levels on the values of $OR_{\text{bone/diet}}$ are presented in Figs. 1A and B. Various combinations of levels were studied with calcium ranging from 0.4 to 2.4 per cent and phosphorus from 0.4 to 2.0 per cent. As shown in Fig. 1A, the OR value generally

Fig. 1A Effect of dietary calcium on $OR_{\text{bone/diet}}$ values at varying dietary levels of phosphorus

Fig. 1B Effects of dietary phosphorus on $OR_{\text{bone/diet}}$ values at varying dietary levels of calcium

Fig. 2A. Effect of dietary calcium on $OR \div \text{per cent calcium}$ at varying dietary levels of phosphorus

Fig. 2B. Effect of dietary phosphorus on $OR \div \text{per cent calcium}$ at varying dietary levels of calcium

increased with the calcium content of the diet. There seemed to be little change in the OR value at 0.7–1.3 per cent phosphorus between calcium levels of 0.4–1.0 per cent. Roughly, a change from 1 to 2 per cent calcium (2-fold) caused an increase of 1.5-fold in the OR value.

Fig. 1B shows that the OR value decreased as the phosphorus content of the diet was increased at given levels of calcium. In general, when the phosphorus level was increased from 0.4 to 1.2 (3-fold) the OR value was decreased by a factor of about 1.5.

A consideration of some interest is the degree to which the body burden of ingested radiostromium can be decreased by dietary supplementation with uncontaminated calcium³. The prediction of such a reduction is reflected not by the value of OR but rather by the value of $OR \div \text{per cent calcium}$. Therefore, the data have been so expressed in Figs. 2A and B. In Fig. 2A it is noted that as the calcium content increased from 0.6 to 2.4 per cent (4-fold) the $OR \div \text{per cent calcium}$ decreased by a factor of about 2.3. The effect of changing the concentration of phosphorus is shown in Fig. 2B. At calcium levels of 0.6–1.5 per cent the slopes of the curves were similar and as the phosphorus content varied from 0.4 to 1.2 per cent (3-fold), the $OR \div \text{per cent calcium}$ decreased by a factor of 1.5; at the 2.4 per cent level of calcium the effect was smaller giving a comparative factor of decrease of about 1.2.

It was of interest to determine the practical extremes at which these effects were demonstrable. Accordingly an investigation was carried out using an experimental diet containing 3 per cent calcium and 3 per cent phosphorus. The results are shown as single points in Figs. 1A to 2B; the OR value was 0.30 and the $OR \div \text{per cent calcium}$ was 0.10, which represented a reasonable fit with the other data as far as could be determined.

Although previous experience had indicated that short-term investigations of this nature do reflect long-term behaviour, it is satisfying to note the close agreement with data based on a 94-day feeding period recently published⁴; Harrison's experiments compared diets of 0.56 and 1.1 per cent dietary calcium at a phosphorus-level of 0.66 per cent and gave values of $OR \div \text{per cent calcium}$ ratios of 0.41 and 0.28, respectively. These compare with values of 0.40 and 0.25 as taken from Fig. 2A. In general the present findings are not in disagreement with the limited number of values and comparisons that are to be found in the literature^{3-5,8}.

It is not the intention here to discuss the reasons for this behaviour. Many factors are undoubtedly operative; in particular, any effects on gastrointestinal absorption and renal excretion. The work recorded here was done with growing animals since this phase is of most interest as regards potential harm from deposited radionuclides. There is an indication that mature animals respond somewhat differently⁴. Also, since the OR value is markedly higher in the very young than in the older individual, the considerations presented here become less applicable with increasing age.

Perhaps the important feature of the investigation is the demonstration that, in the growing rat, the OR value tends more or less regularly to increase with increasing dietary calcium and to decrease with increasing dietary phosphorus. The minimum body burden of ^{90}Sr would be attained if the calcium level of the diet were increased to a maximum by use of uncontaminated calcium and if, at the same time, the phosphorus level were also increased to a maximum. At levels of calcium between about 0.4 and 1.0 per cent and at phosphorus concentrations of 0.7–1.3 per cent, the decrease in body burden of ^{90}Sr would be expected to be roughly proportional to the increase of dietary calcium. At higher levels of calcium and lower levels of phosphorus an increased calcium would lower the body burden of ^{90}Sr to an extent less than proportional. The extent to which levels of ^{90}Sr in the human infant are affected by dietary calcium and phosphorus is not clearly known.

BIOLOGY

Occurrence of *Salvinia auriculata* Aublet on the Congo River

THE floating water fern *Salvinia auriculata* Aublet has caused considerable anxiety by its rapid spread on the newly formed Kariba lake in Rhodesia¹⁻³.

The possibility therefore of the plant spreading to other man-made lakes is a matter of great concern.

This danger is of particular importance to West Africa, where the Volta lake is already filling, and a large lake is due to be formed on the River Niger. Both these river

basins at present appear to be free from both *S. auriculata* and the equally important water hyacinth, *Eichhornia crassipes* Solms.

Therefore the recent discovery (in October 1964) that *S. auriculata* is abundantly present on the Congo river in association with the well-established *E. crassipes* indicates a significant hazard to other countries. Floating masses of hyacinth enclosing *Salvinia* plants are discharged into the Atlantic where some individuals may survive to be accidentally or even deliberately carried elsewhere.

That the presence of *S. auriculata* on the Congo is relatively recent is indicated by botanical collections made on the Congo in 1957 by Lebrun⁴ which included specimens of *S. rotundifolia*, a less economically important species, while *S. auriculata* was not observed.

This collection and two others by Wagemans in 1958, also from the Congo, were all identified by Compère⁵ as *S. rotundifolia*. This identification has since been confirmed by Jarrett⁶ at Kew.

The collection of *S. auriculata* was made by me at, and a few miles above, Leopoldville. Large amounts of the plant were observed as small clumps apparently broken off from larger mats upstream. The material was in the 'tertiary' or folded leaf form and carrying abundant sporocarps. The *Salvinia* was to be found among the numerous clumps of hyacinth stranded on islands in the river and along the bank.

Vigilance by countries within range of the Congo would appear to be desirable so that any isolated introductions of either *S. auriculata* or *E. crassipes* can be readily recognized and rapidly exterminated.

That this hazard is real is shown by the recent (possibly deliberate) introduction, it is believed from the Congo, of *E. crassipes* to Senegal, where action is being taken by the Department of Agriculture at Dakar⁷ to eradicate the weed.

Air Ion Effects on the Oxygen Consumption of Barley Seedlings

IN previous work we demonstrated that exposure of higher plants such as *Avena sativa* and *Hordeum vulgare* to (+) or (-) air ions generated in a pollutant-free atmosphere produced a statistically significant increase in growth under laboratory conditions as well as under greenhouse conditions^{1,2}. Since then, our interests have been focused on the biochemical mechanisms involved in air-ion-enhanced growth. It was found that (+) or (-) air ions materially increase the biosynthesis of cytochrome c and other iron-containing enzymes^{3,4}. We have postulated that the increased concentration of these enzymes may be an important metabolic factor in making possible the accelerated growth-rate regularly observed in ionized air⁴. If this is so, one would expect to find evidence of increased respiratory activity in ion-treated plants. The experiments described here were performed to detect such an increase.

Barley seeds (*Hordeum vulgare* var. 'Musashino') were soaked in distilled water and aerated for 3-5 days. Germinated seeds with several roots 1-2 cm long, but without an emerging coleoptile, were placed on 'Cashmiron' wool moistened with distilled water in a plastic Petri dish. Each of three dishes containing 30 seeds was placed in a plastic ion chamber⁵. The seeds were exposed in the dark

to air-ion densities of 4.5×10^7 (-) ions/cm²/sec; 4.0×10^7 (+) ions/cm²/sec or to normal non-ionized air. At stated intervals 5 seedlings were collected from each chamber and their oxygen consumption was measured by conventional manometric methods at 30° C (ref. 6) repeating each determination three times. Next, the seedlings were dried, first in an oven at 60° C, then over calcium chloride in a desiccator, and they were weighed.

Even as early as 24 h after the start of exposure to air ions, there was a clear-cut increase in oxygen consumption of the treated seedlings as compared with the control (Fig. 1) and the percentage increase at each time-interval remained relatively constant throughout the 96-h period of observation. Evidently an increased oxygen consumption is a significant element in the response of higher plants to treatment with air ions. This finding is compatible with data cited later obtained during the course of experiments on iron chlorosis.

First, it was observed that the development of iron chlorosis in seedlings cultivated in iron-free nutrient solution is markedly accelerated by exposing the seedling to air ions of either charge³. As the concentration of chlorophyll drops at the onset of chlorosis there is a marked rise in the concentration of cytochrome c (as determined by spectrophotometric absorbance and the weight of protein and iron in the extracted cytochrome c fraction)⁴. When seedlings are grown in an iron-containing medium and are exposed to positively or negatively ionized atmosphere during growth, the typical ion-induced acceleration in growth rate is accompanied by stimulation of cytochrome c synthesis, but chlorosis fails to develop and there is no essential difference in the concentration of chlorophyll between exposed and control plants.

Next, studies were made on the effects of gaseous ion on the active and residual iron content of barley seedling during the course of iron chlorosis⁷. Active iron is the fraction concerned with the production of chlorophyll; it is contained in the chloroplasts and is soluble in hydrochloric acid^{8,9}. Residual iron occurs outside the chloroplasts; it is not concerned with chlorophyll production nor is it soluble in 1 N hydrochloric acid. Air ions of either charge induce a significant decrease in active iron content of the seedlings as the chlorophyll content declines. At the same time there occurs an increase in residual iron and the cytochrome c fractions of the seedlings. There is evidence that the rise in residual iron content involves not only cytochrome c but other cytochromes and iron-containing enzymes as well.

Our present working hypothesis, based on earlier experimental results and compatible with the work reported here, suggests that one part of iron within the seed exists in a non-specific form and can be used as required for any purpose (free-state iron). When seeds are soaked in water some of the iron is diverted to the enzyme system concerned in germination. The remainder of the free

Fig. 1. The effect of exposure to (+) or (-) air ions on the oxygen consumption of barley seedlings. Each point represents 3 determinations and the vertical bars are 95 per cent confidence intervals. ●, Negative; ■, positive; ▲, control.

ate iron is used in a balanced fashion for cytochrome synthesis and for synthetic processes leading to chlorophyll formation. If the seeds are grown in an iron-free medium and are exposed to dense atmospheres of $(-)$ $(+)$ air ions, the balance normally prevailing between the two processes is upset; iron is used preferentially for the production of cytochromes and other iron-containing enzymes with the result that insufficient iron is available for the synthesis of chlorophyll and in consequence chlorosis develops.

Under the conditions usually obtaining in Nature, external stores of iron are available, the normal pattern of chlorophyll synthesis prevails and chlorosis is avoided. Here, too, the synthesis of cytochrome and other iron-containing enzymes is stimulated by air ions and the plant provided with metabolic equipment essential for the support of an increased rate of growth. That the enzymes are actually utilized for this purpose is evidenced by the increased rate of oxygen consumption reported in this communication. We are inclined to the belief that the effect of air-ion action in higher plants may be the regulatory systems which control iron metabolism in the seed and young seedlings⁷.

Presence of Plant Growth Substances in Earthworms demonstrated by Paper Chromatography and the Went Pea Test

REPORTS have been published describing increases in growth and vigour of pasture in New Zealand following the experimental transplantation of lumbricid earthworms of the species *Allolobophora caliginosa* into soils where they were not normally found¹⁻³. Fourteen species of Lumbricidae are known in New Zealand, although the family is not native to the region⁴. Since they have been introduced accidentally during the past hundred years or so there has not been sufficient time for them to spread by natural means to all areas under grass. The increased

pasture yields may be due to the presence of plant growth-promoting compounds elaborated by earthworms and secreted by them into their casts and thus into the soil. A similar suggestion was, in fact, advanced by Hopp and Slater⁵, who found in pot experiments that the addition of both living and dead earthworms was associated with increased growth of the test plants.

The application of paper chromatography to earthworm extracts has shown the presence in them of indole compounds, some of which when examined by the Went pea test⁶ have displayed biological activity. The method was as follows. Earthworms were killed by brief immersion in water at 45° C and then homogenized in distilled water (100 g/l.). The homogenized preparation was centrifuged and the supernatant fluid was removed for solvent treatment without pH adjustment. For each species examined the pH was about 6.3. The fluid was extracted twice into peroxide-free diethyl ether and the combined extracts were evaporated in a current of air, leaving residues, which were taken up in water and filtered. The filtrate was then extracted with ethyl acetate which was in turn evaporated, leaving a tarry deposit. The tar-like material was largely eliminated by further extraction with water and filtration. The filtrate was finally extracted with ethyl acetate which was evaporated to 0.1 ml. Of this volume one-tenth was used for spot detection, and the remainder was applied as a streak a few centimetres away on the starting line, to provide material for the biological test. Ascending chromatograms were developed for 6 h at 22° C in 8 : 1 : 1 isopropyl alcohol, aqueous ammonia and water⁷ and indole substances detected by the modified Ehrlich reagent of Jepsen⁸. After drying, the paper was cut 0.5 cm above and below the corresponding spot position, while spot-free areas were cut into strips of 2 cm width. Strips were eluted by shaking with 20 ml. distilled water and the extracts assayed by the pea test.

For each of the species examined, there were several indole compounds present, but only one was biologically active. The results are summarized in Table 1; the R_F figures shown are mean values derived from several tests.

It is apparent that the biologically active compound is different in each of these species. With four of them the separate identity of the compounds was confirmed by the pea test. Aqueous extracts of earthworms were tested in serial dilution against pea shoots. The curvatures obtained were plotted against the log of the concentration of extract and the straight lines so derived differed in slope from each other and from indolyl-3-acetic acid (IAA). The mean angular differences from IAA were as follows: *A. caliginosa*, + 15°; *L. rubellus*, + 30°; *E. foetida*, + 43°.

As well as earthworms, two species of common garden slugs have been found to contain plant growth substance. Centrifuged homogenates of *Agriolimax reticulatus* and *Milax gracilis* both yielded pea curvatures similar to those of earthworms at the same concentration. Solvent extracts were prepared in the same way as for earthworms; chromatograms of these produced, in the case of *M. gracilis*, an intense indigo spot which was not biologically active, whereas the pea responses were obtained from the region of R_F 0.62-0.76, where no indole compounds were detected. With *A. reticulatus*, on the other hand, no indole colours developed, while pea curvatures were obtained at R_F 0.27-0.40.

Table 1. INDOLE COMPOUNDS PRESENT IN EARTHWORM EXTRACTS

Species	Positive in the pea test R_F value	Ehrlich colour	Ninhydrin reaction	Not responsive in the pea test R_F values
<i>Allolobophora caliginosa</i>	0.59	Indigo-brown	+	0.47, 0.78
<i>Allolobophora longa</i>	0.09	Red-brown	—	0.69, 0.71
<i>Lumbricus rubellus</i>	0.54	Violet	—	0.68, 0.88
<i>Lumbricus terrestris</i>	0.25	Violet-brown	—	0.65
<i>Eisenia foetida</i>	0.73	Violet	+	0.35
<i>Dendrobaena rubida</i>	0.45	Indigo	—	0.08, 0.14, 0.65, 0.82
Indolyl-3-acetic acid	0.50	Purple	—	

Apart from the possible effects on plant growth of these substances secreted by earthworms, they might well subserve a useful function in solving problems of taxonomy in the Oligochaeta. For example, among the Lumbricidae it may be possible by further investigation of the growth substances to establish the validity of species such as *Dendrobaena subrubicunda*, the identity of which is now in doubt⁶.

Promotion of Germination in Light-requiring Seed by Chloramphenicol

In this laboratory we are investigating germination processes in light-requiring seeds of *Lactuca sativa* L. (var 'Grand Rapids') including protein and nucleic acid synthesis in relation to the photocontrol of germination. During this investigation the effects of some inhibitors of protein synthesis have been examined. This communication reports certain results which have been obtained with chloramphenicol.

Our sample of seeds (batch No. 18639, of the 1964 harvest, from Ferry-Morse Seed Co.) gives approximately 10 per cent germination in darkness at 24°C, the maximum being reached after 20 h. 95–98 per cent germination is achieved following irradiation with red light (1 min at 120 $\mu\text{W}/\text{cm}^2$) given 1.5 h after the start of imbibition.

In preliminary experiments, when seeds were incubated on filter paper moistened with chloramphenicol solutions (750–3,500 $\mu\text{g}/\text{ml}$) at 24°C, a marked stimulation of germination in darkness was noted. This stimulation was much more pronounced if the seeds were infiltrated with the chloramphenicol solutions under reduced pressure. In this treatment, the seeds were allowed to imbibe on filter paper moistened with the test solutions for 1.5 h. They were then placed in approximately 10 ml. of the solution (or water, in the control) in a tube which was evacuated three or four times until the seeds failed to rise to the top of the liquid. They were then returned to filter paper wetted with the appropriate solution and the germination percentages were measured after 24 h in darkness at 24°C. All manipulations were carried out under a green safelight. Fig. 1 shows that the amount of germination in darkness increases linearly with chloramphenicol concentration over the range 500–3,000 $\mu\text{g}/\text{ml}$. These results have been confirmed, and we have also been informed that other workers found slight stimulation of dark germination by low concentrations of chloramphenicol¹.

Far-red light markedly reduces the promotive effect of chloramphenicol. To show this, seeds were irradiated, after one hour's imbibition and again after infiltration, with far-red light for 5 min at 230 $\mu\text{W}/\text{cm}^2$, and then returned to darkness. The lowest curve of Fig. 1 represents the results of this treatment. In further experiments it was found that chloramphenicol was ineffective in causing germination in darkness if the seeds were allowed to imbibe on water for 24 h prior to application of this chemical. In these experiments also, the seeds were infiltrated after the period on water and were incubated on the chloramphenicol solutions for 24 h before counting.

It is well known that the response of 'Grand Rapids' seeds to a given energy-level of red light decreases if the

imbibed seeds are held in darkness for some time before irradiation². This is described as skotodormancy. The curve in Fig. 2 illustrates this for our sample of seed. The other curve in Fig. 2 shows the effect of chloramphenicol on the development of skotodormancy. In these experiments seeds were kept on filter paper wetted with 2,000 $\mu\text{g}/\text{ml}$. chloramphenicol, without infiltration, for varying lengths of time in darkness. The ungerminated seeds were removed, infiltrated several times with water and spread on papers moistened with water. They were then illuminated with red light for 1 min at 120 $\mu\text{W}/\text{cm}^2$ and returned to darkness. Control seeds were manipulated

Fig. 1. Effect of chloramphenicol on germination of 'Grand Rapids' lettuce seeds at 24°C. Figures represent the means of 4 replications. Δ, Seeds exposed to red light (1 min at 120 $\mu\text{W}/\text{cm}^2$) 1.5 h after start of imbibition; ○, seeds maintained in darkness; ●, far-red treated seeds

Fig. 2. Effect of chloramphenicol on skotodormancy. ●, Chloramphenicol-treated seeds (2,000 $\mu\text{g}/\text{ml}$); ○, water-imbibed seeds

narily except for the exposure to chloramphenicol. Germination percentages were determined 24 h after irradiation. Fig. 2 shows that seeds treated with chloramphenicol retain their sensitivity to light even after 24 h in darkness. It is unlikely that residual chloramphenicol in the seeds is acting additively with red light, for in further experiments the washing period after treatment with the chemical was prolonged to 24 h without any accompanying loss of response to red light.

In our experiments we have found no appreciable stimulation of germination in darkness by chloramphenicol one at concentrations lower than 500 $\mu\text{g/ml}$. However, these levels do increase the ability of very low concentrations of gibberellic acid (GA_3) to promote dark germination. For example, 20 $\mu\text{g/ml}$ GA_3 induced approximately 50 per cent germination in darkness, but this value was increased to the order of 70 per cent when the gibberellin was combined with 150–500 $\mu\text{g/ml}$ chloramphenicol. The effect of much lower concentrations of GA_3 (5 $\mu\text{g/ml}$) was similarly enhanced.

Two hypotheses concerning the promotion of germination in darkness by chloramphenicol can be suggested. First, this substance might have a positive promotive effect such that normal control by way of the phytochrome system is by-passed. On the other hand, although its action may be dependent on phytochrome it might primarily arrest an inhibitory process which commences in darkness when the seeds imbibe water. The results presented here lead us to favour the second suggestion. Since short irradiation with far-red light reduces the effect of chloramphenicol, it is not likely that this substance behaves entirely in a positive promotive fashion unless it acts directly on the phytochrome system to convert P_R to P_{FR} , which does not seem plausible. That chloramphenicol is almost completely ineffective if applied to the seeds after a 24-h delay on water, also supports this conclusion. It seems probable, from the experiments with far-red light, that germination even in chloramphenicol-treated seeds is still to some extent under phytochrome control. Now, dark-imbibed seeds are thought to contain a small proportion of phytochrome in the active (P_{FR}) form. This is inferred from the observation³, which we have confirmed, that germination, in darkness, of control seeds on water is substantially reduced by a short exposure to far-red radiation. We would suggest, therefore, that the effect of the low level of P_{FR} present in dark-imbibed seeds is fortified by chloramphenicol.

The question now arises as to the mechanism of action of chloramphenicol. This substance has been shown to inhibit protein synthesis in a number of plant systems including seeds. Young and Varner⁴, for example, found that chloramphenicol strongly reduces amylase and phosphatase synthesis in pea seeds although germination still proceeds. It is possible, then, that chloramphenicol acts in a similar manner in lettuce seeds and here prevents the development of some inhibitory system in which protein synthesis is involved. It is assumed that this inhibitory system normally impedes the action of the low level of P_{FR} . Although this has not yet been shown directly we have found, using ^{14}C -labelled leucine and ^{14}C -orotic acid, that there is indeed protein and RNA synthesis occurring in dark-imbibed seeds even though they do not germinate. Moreover, there are indications that this protein synthesis is almost completely confined to the endosperm and cotyledons. Further evidence of protein synthesis in darkness comes from our finding of a different protein pattern (using disc electrophoretic separation on polyacrylamide gel^{5,6}) in the soluble proteins of dark-imbibed seeds from that in dry or germinating seeds.

The hypothesis developed above, that the low level of P_{FR} in dark imbibed seeds is antagonized by an inhibitory system preventing germination, might explain why chloramphenicol is ineffective if applied to seeds which have previously been kept on water for 24 h. Under these

conditions, not only does the inhibitory system assume dominance but there is also a loss of P_{FR} by dark reversion or destruction. The possibility also arises that skotodormancy is caused by an active inhibition during darkness.

We have implied in the foregoing discussion that chloramphenicol does not directly affect the phytochrome system but that it acts to relieve some sort of inhibitory process. One further possibility should, however, be considered—that chloramphenicol prevents the loss of P_{FR} , occurring by conversion to P_R or by dark destruction⁷. In either case the result would be the maintenance of the low level of P_{FR} . Some evidence has been presented³ that P_{FR} , if maintained even in small proportions for an extended duration, can induce germination over several days. Since the effect of chloramphenicol in our experiments is apparent after 20 h it does not seem likely that it can act only to preserve the low level of P_{FR} .

In conclusion, we believe that the foregoing results indicate the possibility that germination in light-requiring lettuce seeds is under the control of two systems, a promotive one governed by phytochrome and an inhibitory one which commences after imbibition and for which protein synthesis is required. It is interesting to note here that birch seeds, for which there is good evidence against an active inhibitory process in darkness⁸, show no response to chloramphenicol in darkness.

Oxidative and Biosynthetic Utilization by Human Spermatozoa of a Metabolite of the Female Reproductive Tract

In vitro investigations of the metabolism of mammalian spermatozoa have amply demonstrated their ability to utilize a variety of glycolysable and oxidizable substrates¹. No information is, however, available on the metabolism of spermatozoa within the female reproductive tract. If, as is probable, the epithelial cells use up not only the glucose supplied by the circulatory system, but also oxidizable intermediates such as pyruvate and lactate, the spermatozoa in contact with those cells would have to oxidize their endogenous reserves of lipid material, provided that the oxygen tension in the various regions of the tract is adequate to support the aerobic metabolism of the spermatozoa. In the absence of external substrates the conditions in the female genital tract would not be favourable for the survival of spermatozoa for prolonged periods of time. Whereas this may not affect fertility in animal species in which mating occurs at the time of oestrus, with rapid ascent of an adequate number of spermatozoa, a limited survival capacity due to the lack of substrates may affect the prospects of fertilization in man.

During human fertility investigations, motile spermatozoa have been found in cervical mucus 12 h and even several days after coitus, although in 'hostile mucus' motility is lost rapidly². Among a number of factors which may be involved, the possibility suggests itself that the secretions of certain sites of the female reproductive tract may contain metabolites which are not utilized by the

epithelial cells of the tract but can be taken up by spermatozoa. This hypothesis is suggested by the report of Kurzrok and Birnberg³ of the occurrence of glucosamine in human cervical mucus at the time of ovulation. Since hexosamines are not known to serve as substrates of spermatozoa, experiments were designed to test the ability of spermatozoa to metabolize glucosamine.

Suspensions of washed human spermatozoa in Krebs saline were incubated under aerobic conditions with D-glucosamine-1-¹⁴C and the 'respiratory CO₂' was collected and counted. This technique had been found sufficiently sensitive to measure the rates of oxidation of such substrates as glucose, pyruvate and acetate in human sperm suspensions using normal cell counts which are too low to permit measurements of gaseous exchanges⁴. As shown in Table 1, human spermatozoa produced ¹⁴CO₂ from D-glucosamine-1-¹⁴C at somewhat lower rates than from glucose-¹⁴C (randomly labelled). The production of ¹⁴CO₂ from glucosamine was suppressed in the presence of non-radioactive glucose, whereas glucosamine did not inhibit the oxidation of glucose-¹⁴C. When bull spermatozoa were tested under similar experimental conditions and with the same batch of radioactive substrates, different results were obtained; whereas glucose stimulated the respiration of bull spermatozoa and its carbon appeared in the respiratory carbon dioxide, the respiratory rate in the presence of glucosamine remained at the endogenous level and only negligible amounts of ¹⁴CO₂ were produced. Since brain extracts are known to phosphorylate glucosamine^{5,6}, a respiring hamster brain homogenate was incubated with glucose-¹⁴C and with D-glucosamine-1-¹⁴C. Like bull spermatozoa, hamster brain actively oxidized glucose, but failed to liberate ¹⁴CO₂ from glucosamine.

In recent investigations in this laboratory it was found that human spermatozoa utilize glucose and acetate as precursors in the biosynthesis of glycerolipids⁷, extending previous reports on the biosynthesis of lipids by bull⁸ and fish spermatozoa⁹. The possibility of a biosynthetic pathway of glucosamine was therefore examined. Human spermatozoa, freed from seminal plasma by centrifugation, were suspended in Krebs saline and incubated with D-glucosamine-1-¹⁴C for 4 h at 37°. After re-isolation and washing of the cells in Krebs saline containing unlabelled glucosamine, the lipids were extracted and purified by the procedure of Folch¹⁰ and fractionated on silicic acid columns. After both aerobic and anaerobic incubation the glyceride and phosphatide fractions were found to be carbon-14-labelled in a pattern resembling the labelling of animal spermatozoa by glucose-¹⁴C. The rate of incorporation of glucosamine into the total lipids of human spermatozoa was of the same order of magnitude as the rate of incorporation of glucose (0.3–0.5 μmoles/10⁸ spermatozoa/h).

Although the metabolism of glucosamine by spermatozoa of other species remains to be tested, the preliminary finding of a difference in enzymatic properties between the spermatozoa of man and the bull is intriguing. The intermediary steps of glucosamine breakdown in human spermatozoa are not known at present, but from the observed suppression of the production of ¹⁴CO₂ from glucosamine-1-¹⁴C when glucose was added, it may be presumed that the initial step is a phosphorylation catalysed by a hexokinase of greater affinity for glucose than for glucosamine. This step may be followed by the deamination of

glucosamine-6-phosphate to yield fructose-6-phosphate, reaction known to occur in animal and bacterial systems^{11,12}. The ability of human spermatozoa to channel glucosamine carbon into the glycolytic pathway would account for the oxidation of glucosamine and its incorporation into the glycerol portion of the glycerolipids.

The finding that human spermatozoa can utilize as substrate a metabolite of the cervical secretion is of significance because it shows that the energy metabolism of spermatozoa can be supported within the female reproductive tract. Furthermore, the demonstration of the incorporation of this metabolite into the lipids of spermatozoa suggests that these cells may replenish the reserves while passing through certain sites of the female tract. These observations also open up an approach to the study of the phenomenon of capacitation. As a working hypothesis it is suggested that capacitation is the result of the uptake by spermatozoa of a metabolite of the female reproductive tract, enabling the biosynthesis of a component necessary for the functional integrity of spermatozoa.

Electromagnetic Recording Diver Balance

THE use of the Cartesian principle in a very sensitive device for measuring manometric reactions was suggested by Linderström-Lang in 1937 (ref. 1). In the hands of Holter² the diver method was developed into a reliable and versatile technique; further increase in the sensitivity was accomplished by Zeuthen³.

The concept of reduced weight, RW (= submerged weight) was introduced by Linderström-Lang and Holt in connexion with density gradient work⁴. Subsequently Zeuthen⁵ invented a Cartesian diver balance on which determinations of RW may be made.

The diver balance has so far only been used in biologic work, but in this field it has turned out to be a very useful tool.

Its applications include the determination of water permeation, using D₂O as a tracer^{6–10}. Exchange studies with the Cartesian diver balance are rather tedious, as an automatically recording diver balance would therefore be a great advantage in this work. To meet this requirement we have constructed an electromagnetic diver balance (Fig. 1). The diver is made either of plastic (polyethylene) or of glass; in either case a small piece of magnetic material ('Koerzit T') is contained in the lower end of the diver. The RW of the finished diver must be adjusted so that it rises to the surface in the appropriate medium; the force required to pull it down must not, on the other hand, exceed the maximum force of the electromagnetic magnet (see below).

An ordinary photocell cuvette, containing medium as diver, is placed in the light path between a lamp and photocell. The current in a magnetic coil below the cuvette is passed through an amplifier controlled by the lig

Table 1. OXIDATION OF GLUCOSE AND GLUCOSAMINE BY SPERMATOZOA

Fig. 1. Photograph showing part of the diver balance set-up. In the cuvette a diver is floating, loaded with a frog's egg

Fig. 2. Diagram of the operating principle of the electromagnetic diver balance

reaching the photocell (Fig. 2). The current is proportional to the amount of light, and the diver will sink in the cuvette until the current in the coil just balances the buoyancy. When loaded, less current is required. The decrease in current, proportional to the load, is registered on a recorder. The unit, comprising cuvette, photocell, lamp, and electromagnet, is submerged in a water bath. Besides weighings and permeability (diffusion) determinations the balance may also be used to follow gasometric reactions. If a small capillary, sealed with a fluid stopper (like the Cartesian diver), is placed on the balance, the change in RW associated with consumption or production of gas may be registered.

The range of the balance shown in Fig. 1 is about 10–300 μg . More sensitive balances may be constructed, but great demands must in that case be made on the temperature regulation of the water bath. No upper limit seems to obtain, and there seems to be no reason why a diver balance for RW determination on whales cannot be made, should the need arise.

Note added in proof. After the present communication was submitted for publication, a paper has appeared (Brzin, M., Kovic, M., and Oman, S., *Compt. Rend. Lab. Carlsberg*, 34, 407; 1965) describing an electromagnetic

recording diver balance. This device is, however, manually controlled and not automatic like that described here.

Photo-induced Hydroxylation of Cinnamic Acid in Gherkin Hypocotyls

THE influence of light of different spectral regions on the synthesis of hydroxycinnamic acids in the hypocotyls of gherkin seedlings has been described previously¹. This phenol synthesis can be stimulated considerably by supplying segments from the hypocotyls with *trans*-cinnamic acid. In the latter case about 95 per cent of the end-product consists of a glucose ester of *p*-coumaric acid, as was determined with paper chromatography. Light stimulates the conversion of cinnamic acid to *p*-coumaric acid. The occurrence in plant material of a hydroxylase which catalyses this reaction has been demonstrated by Nair and Vining². They showed that tetrahydrofolic acid and a reduced pyridine nucleotide were necessary to obtain maximum enzyme activity. The feeding experiments with cinnamic acid enable us to investigate how far the accumulation of hydroxycinnamic acids in the hypocotyls of intact seedlings in response to light is determined by changes in hydroxylase activity.

To examine whether enzyme synthesis is involved we have used cycloheximide (actidione), a drug that inhibits the transfer of amino-acid from sRNA to polypeptide^{3,4}. The following experiment was performed. Hypocotyl segments, 5 mm in length, were cut immediately below the plumular hook of 3-day-old gherkin seedlings (*Cucumis sativus* 'Venlose niet plekkers', strain 'Tercken VI'), grown in the dark. Lots, of 30 segments each, were floated on 10 ml. distilled water in Petri dishes, kept in darkness for 2 h, and then transferred to a cabinet with blue light (700 $\mu\text{W}/\text{cm}^2$). To different duplicate samples 50 μg cycloheximide was added at the following times: 2 h before transfer to the light, immediately before transfer to the light, and after 2, 4 and 6 h in the light, respectively. All segments remained in the light during 24 h. Afterwards the cycloheximide-treated lots were washed with distilled water, and all the samples were transferred to Petri dishes with 10 ml. of 10^{-3} M *trans*-cinnamic acid and 1 per cent glucose in water (pH 5.0). Fig. 1 gives the amounts of *p*-coumaric acid glucose ester that accumulated in the segments during the next 24 h, in which they were kept on the precursor solution in darkness. To two of the four lots that had not previously been treated with the drug, 50 μg cycloheximide was added in the precursor solution. The average value obtained for these samples is given by the closed symbol in Fig. 1. Hydroxycinnamic acid esters in this and in the following experiments were determined as described previously¹. Each point in the graphs represents the mean of three experiments, each run in duplicate.

The foregoing experiment excludes the possibility of a direct photochemical reaction involving cinnamic acid. The inhibition by cycloheximide indicates that *de novo*

synthesis of one or more enzymes is involved. Addition of the inhibitor has an effect similar to that found when transferring the seedlings to darkness, as can be seen by comparing Figs. 1 and 2. That the inhibition is not an unspecific effect is demonstrated by the fact that *cycloheximide* has very little effect once light has been given for more than 6 h. Whether this light-induced enzyme synthesis concerns cinnamic acid hydroxylase itself, or one or more enzymes involved in the synthesis of a co-factor, has not yet been established. Evidence that *de novo* synthesis of enzymes plays a part in the increase in phenol synthesis in response to light has also been obtained for chlorogenic acid in potato tuber tissue⁵ and of anthocyanin in mustard seedlings⁶.

The influence of light quality, light intensity and duration of irradiation on the conversion of cinnamic acid into *p*-coumaric acid in hypocotyl segments is shown in Fig. 2. For these experiments the same light and filter combinations were used as for those with intact seedlings¹. Duplicate lots of 30 segments each were floated on an aqueous solution of 10^{-3} M *trans*-cinnamic acid and 1 per cent glucose (pH 5.0), irradiated for the times indicated in the graphs, and afterwards kept in the dark until 24 h from the beginning of the irradiation.

In a number of aspects the results are remarkably parallel with those relating to the effects of light on the accumulation of hydroxycinnamic acids in the hypocotyls of intact seedlings¹.

(1) In all three wave-length regions the induction is an increasing function of the duration of irradiation up to a certain limit. This limit of about 8 h is fairly independent of light quality and light intensity. It may be that this has some bearing on the problem of photoperiodism.

Fig. 1. Effect of *cycloheximide* on cinnamic acid hydroxylation in gherkin hypocotyl segments induced by blue light ($700 \mu\text{W}/\text{cm}^2$). Segments were floated on distilled water and irradiated for 24 h. *Cycloheximide* ($5 \mu\text{g}/\text{ml}$) was added to different lots at the times indicated in the graph. The points give the amounts of *p*-coumaric acid accumulated in the segments during the next 24 h in darkness from aqueous solutions of 10^{-3} M *trans*-cinnamic acid and 1 per cent glucose (open symbols) and 10^{-3} M *trans*-cinnamic acid, 1 per cent glucose and *cycloheximide* ($5 \mu\text{g}/\text{ml}$) (closed symbol).

Fig. 2. Accumulation of *p*-coumaric acid during 24 h in hypocotyl segments floated on an aqueous solution of 10^{-3} M *trans*-cinnamic acid and 1 per cent glucose as a function of duration of irradiation with blue, red and far-red light.

(2) Blue light is much more effective than light of the other wave-length regions, the induction being an increasing function of the light intensity.

(3) The induced hydroxylase activity is always smaller in the basal part of the hypocotyl than in the apical part, as was revealed in experiments with segments excised from different parts of the hypocotyl⁷. The spectral distribution of the light sensitivity did not alter significantly over the length of the hypocotyl. Therefore, if more than one pigment is involved we may expect a rather similar distribution.

An important difference between light-induced phenol synthesis in hypocotyls of intact seedlings and induced hydroxylase activity in hypocotyl segments is that short irradiations only on the former process have a relatively pronounced effect¹. Moreover, the relative effectiveness of blue, red and far-red light in inducing hydroxylase activity in segments is more in agreement with the induced phenol synthesis in hypocotyls of decotyledonized seedlings than in those of intact plants. A recent finding that a much higher stimulation of hydroxylase activity in segments can be obtained when the intact plant receives the short light treatment instead (10 min), and the segment to be excised remains part of the plant for at least 1 h after the light treatment, may have some bearing on this⁷. Excision before or covering during the irradiation of the cotyledons has a lowering effect. Therefore, besides hydroxycinnamic acid precursors, other transportable factors are probably involved in the light-induced phenol synthesis. They may play a role in the induction of enzymes or in the modification of their activity.

Feeding with phenylalanine also results in increased synthesis of *p*-coumaric acid in hypocotyl segments. In this plant no stimulation has so far been obtained with a number of other hydroxycinnamic acid precursors⁸; glucose, quinic acid, shikimic acid, phenyllactic acid and

tyrosine. It may be that at this stage of development the seedling depends for its phenol metabolism on the supply of phenylalanine originally present in the cotyledons. We do not yet know whether in the gherkin hypocotyl the phenylalanine deaminase activity is already high enough or is also increased by light to meet the demands for cinnamic acid under all circumstances. Photo-induced hydroxylation of this compound seems to be determined by local factors and by influences from other parts of the plant. There is a striking correlation between enzyme activity and accumulation of phenols in a particular part of the hypocotyl⁷. This points to an important controlling function of the hydroxylase step in hydroxycinnamic acid metabolism and in cell elongation, so far as the latter is regulated by phenols⁸.

Histological Investigations of the Mechanism of Sterility Induced by Deuterium Oxide in Mice

DURING investigations in which normal females were mated to male mice treated with deuterium oxide, it has been shown that D₂O produces sterility in the males^{1,2}; however, the site of the damage has not been demonstrated. Since embryonic death after implantation did not increase in such females, cleavage stage embryos were examined 18–72 h after mating³. Most of the embryos present in the oviducts were either one-celled or, though 'multicellular', were abnormal and degenerating; few normal embryos were found. These results did not indicate whether developmental failure was due to failure of the sperm to fertilize the egg or to a failure of the fertilized egg to develop. The experiment reported here utilized standard histological techniques to demonstrate clearly that the previously observed pre-implantation death is due to the failure of the sperm to fertilize the egg, not to subsequent abnormal cleavage of the fertilized egg.

C₅₇ male mice from the University of California Cancer Research Laboratory, 10–14 weeks old at the beginning of the experiment, were used. This inbred strain has been shown to be more sensitive to the sterility-producing effects of D₂O than Swiss strain mice, which are random bred⁴. Because C₅₇ males are known to have a high innate sterility, they were tested for fertility before the start of the experiment, and only those males which sired two viable litters were used. D₂O was given at the concentration of 30 per cent by volume in the drinking water *ad lib*. At the end of treatment for 4 weeks, water was given instead of deuterium oxide as drinking water. Control males, mated weekly, were maintained under conditions identical to those of the experimental animals except that they drank water throughout the experiment. All females were virgin Swiss mice, from Simonsen Laboratories, Gilroy, California.

Each male was caged with 8 (later 3) females nightly from 10 p.m. to 9 a.m. At 4-h intervals the females were examined for vaginal plugs. Thus the time of copulation could be estimated within 4 h. As females were mated, they were removed and other females were placed in the cage. Males were killed 12–16 h after mating. Some mated females were allowed to go to term; their litters were examined at birth.

Fig. 1. Effect of D₂O on the number of fertilized eggs obtained from females mated to treated males. The number of fertilized eggs as percentage of the total eggs examined, with the standard error of the mean, is presented; also a tabulation of total eggs, fertilized and unfertilized eggs. Those eggs scored as degenerating or undiagnosable are not included in the tabulation.

* The data from females mated to control males were used in the analysis of variance calculations. However, since the sample size for each week was small, the data have been pooled with those from the treated males at zero time.

Oviducts were removed *in toto* and fixed in Bouin's solution. They were embedded in paraffin, serially sectioned at 10 μ , and stained with haematoxylin-eosin. All sections of each oviduct were examined with a light microscope; magnifications up to times 640 were used. All slides were code-numbered, so that the experimenter did not know whether the eggs came from a control female or one mated to a treated male. Eggs were scored as 'fertilized' if two pronuclei were observed or if a sperm tail and enlarging sperm head were visible in the ooplasm and/or if the orientation, condensation and chromosome position in the oocyte meiotic spindle indicated that emission of the second polar body was in progress or complete. In eggs scored 'unfertilized', an unchanged second meiotic spindle was present in the ooplasm and there was no evidence of sperm head or tail. Fragmented eggs, and those in which the ooplasm showed unusual condensation, were scored as 'degenerating'.

The results are shown in Fig. 1. By two weeks on D₂O, the average number of fertilized eggs had dropped from 5.8 per female (pooled data for females mated with control males and treated males at week zero) to 3.8 per female; after males had been on D₂O for four weeks, no fertilized eggs were obtained from the mated females. A two-way analysis of variance was carried out on the data⁵. The group treated with D₂O was significantly different from the control group ($F_{1,44}=8.5$; $P\leq 0.01$). There was also a systematic change over the eight-week period ($F_{8,44}=4.5$; $P\leq 0.01$), and this change was a function of whether the animals had been treated with D₂O, that is, the interaction between treatment and time was significant ($F_{8,44}=2.6$; $P\leq 0.05$). Table 1 gives the results of the number and size of litters obtained from those females which were

allowed to go to term. From a control average of 7.3 viable offspring per female, there was a decrease to 0.3 offspring per female after two weeks' treatment and to no offspring after three weeks of D_2O administration to the males.

Under the conditions of this experiment, sperm penetration usually occurred within 6-8 h after the females were removed from the males. Thus, by collecting eggs 12 h after copulation, one could be sure that sperm entry would have been effected, yet most eggs should not be old enough to start degenerating. The results presented here clearly indicate that failure of the D_2O -treated males to produce viable offspring, as previously reported, was due to the failure of the sperm to fertilize the egg and not to a failure of the subsequent development of the fertilized egg. These conclusions are supported by subsequent examination of 630 living eggs by phase contrast microscopy.

Histological examination of the testes of D_2O -treated male mice is in progress; initial observations suggest that acrosome formation may be abnormal. However, at present, the mechanism of action of D_2O in producing sterility is not known. Autoradiographic studies of eggs from females mated to D_2O -treated males (in which the sperm are labelled isotopically) and electron microscopy of sperm from D_2O -treated males are also in progress in further attempts to pinpoint the site of action of D_2O .

MICROBIOLOGY

Simplified Technique for Preparative Disc Electrophoresis

THE disc electrophoretic method¹ is becoming an important analytical tool in the study of components of complex mixtures. While engaged in work on the separation of antigenic constituents of connective tissue, we did some experiments to adapt this method to a preparative scale. Our aim was to construct as simple and inexpensive an apparatus as possible. In the course of our experiments we became aware of the publications of Lewis and Clark² and Racusen and Calvanico³ on preparative disc electrophoresis. One of the instruments described by the former investigators seemed, after minor modifications, to be suitable for our purpose. The procedure finally devised differed from that of Lewis and Clark mainly in the use of a 'Sephadex G-200'-sucrose mixture instead of the sample gel⁴ and in the arrangements for eluting the material from the polyacrylamide gel.

The apparatus (Figs. 1, 2 and 3) consists of (A) a 'Perspex' box used as the upper buffer reservoir, (B) a

Fig. 1. Drawing of preparative disc electrophoresis apparatus. E, Upper electrode; A, upper reservoir; C, tube containing the gel system; D, cap covering lower end of C; F, 'Perspex' attachment used for elution; G, brass jig with slot H.

short 'Perspex' tube attached to a hole cut in the centre of A, (C) a 'Perspex' tube with threaded ends, which can be screwed into B, (D) a 'Perspex' cap with a 1-mm hole drilled in the centre, which can be screwed on the lower end of C. The connexions of C to B and D are made water-tight by means of rubber washers. A plastic insert serving as the reservoir for the lower buffer has a flat platinum wire electrode affixed to the bottom centre. A similar electrode, E, attached to a round polyethylene plate, is used for the upper reservoir. F is a short 'Perspex' tubing, which can be screwed on to the top of C. H is a brass jig with a slot, H, 3 mm from one end.

Fig. 3. Jig for cutting gel slices (centre) with cover (right) and 'Perspex' piston (left) used in holding the gel in position during cutting

ise with two projecting pins, which fit into holes in the wall of *G*, is used to close one end of the jig.

Lower and spacer gels were prepared as described by Ornstein and Davies¹. The sample gel was replaced by a suspension of 'Sephadex G-200' in 20 per cent sucrose⁴. The 'Sephadex' suspension was centrifuged for 15 min at 3,000 r.p.m. in an MSE 'Multex' centrifuge and the supernate was discarded. To 5 ml. of the packed 'Sephadex' was added 2 ml. of *tris*-glycine buffer pH 6.7 (ref. 1) diluted 1/10 (TGB) and 1 ml. of the sample previously dialysed against TGB. The use of 'Sephadex' obviated the difficulties sometimes encountered in the polymerization of the sample gel and shortened the time required to set up the experiment.

Electrophoresis was carried out as follows: the centre hole in cap *D* was plugged with a piece of 'Plasticine'. The cap was screwed on the lower end of tube *C* and the tube was clamped in a vertical position. 50 ml. of the lower gel were introduced into *C* and the gel was covered with a 2-mm layer of distilled water. Polymerization was completed in 50–60 min. The water was removed and the lower gel was rinsed with spacer gel in the usual way. 15 ml. of the spacer gel were poured on the lower gel and covered with water as before. Photopolymerization was carried out with a 15 W fluorescent daylight lamp, placed at a distance of 2 cm from *C*. The lamp was moved to the opposite side of *C* after 15 min, and then placed above and close to *C* after another 10 min. The polymerization required approximately 50 min.

The water layer was removed and *D* was unscrewed, after first unplugging the hole. The apparatus was assembled as shown in Fig. 2. The lower reservoir was filled with TGB, the level of the buffer solution being adjusted so that *C* was immersed to a depth of 2 cm. The sample (incorporated in 'Sephadex-TGB') was placed on the spacer gel, followed by 2 ml. of packed 'Sephadex' in sucrose. The latter served to protect the sample from mixing with the buffer solution. TGB, containing 1.5 ml./l. of 0.01 per cent bromphenol blue, was carefully placed over the 'Sephadex'. The total amount of buffer solution in the upper reservoir was 500 ml. Electrophoresis was carried out in a cold room at a constant current of 45 mA and 320 V. The current was adjusted by changing the position of the upper electrode in box *A*. The run was completed in about 4 h. During this time

the bromphenol blue band travelled down tube *C* for 8–9 cm.

Tube *C* was now unscrewed, the gel was rimmed under water and allowed to slide into the cutting jig *G*, the latter being closed with its cover. 3-mm slices were cut with a small hand saw, through slot *H*. A small piece was cut from each slice and placed along the side of a microscope slide coated with 2 per cent Noble agar in veronal buffer pH 8.2, μ : 0.05. Antiserum containing antibodies to the mixture of antigens being separated was placed in the centre trough. Antigens present in sufficient concentration produced lines within 24 h, but final results were read after 4–5 days.

Direct elution of the antigens by suspending the broken-up gel slices in buffer solutions did not give satisfactory results. Elution was therefore carried out by electrophoresis. Slices giving precipitation lines were broken up in a 'Teflon' homogenizer. A piece of dialysis tubing knotted at one end was drawn over *F* and fastened with rubber bands. *F* was filled with TGB and several layers of filter paper were placed at *I*. *F* was screwed on to *C* and the broken-up gel to be eluted was placed on the filter paper and covered with a disc of filter paper on which was placed a small amount of 'Sephadex' (1 mm high). The apparatus was assembled as before and electrophoresis was carried out at 45 mA, 300 V, for 3 h. A test with antigen labelled with ¹²⁵I showed that about 95 per cent of the radioactivity was eluted from the gel during this time. The antigen solution was concentrated by pervaporation and the antigen was identified by diffusion in agar.

We have successfully used this technique to prepare a purified antigen from a complex mixture of rat liver connective tissue antigens. The antigen was separated by preparative disc electrophoresis after preliminary fractionation on a column of 'Sephadex G-100' and treatment with acetate buffer, pH 5.5. A description of this procedure is being prepared. The antigen was concentrated in two gel slices.

The technique described here was also found useful for preparing antibodies to single components of the mixture, without having first to isolate the antigen. The slice containing the desired component was homogenized in borate buffer, pH 8.0, incorporated in Freund's adjuvant and injected into rabbits. Antibodies were detected by diffusion in agar 2 weeks after injection. The difficulty with which proteins are eluted from polyacrylamide⁵ suggests that the gel itself might have adjuvant properties, through a slow release of antigenic material. Weintraub and Raymond⁶ have indeed demonstrated the ability of the gel to enhance antibody production and they have pointed out the advantage of this technique in preparing antibodies to single components of complex mixtures. We were not aware of their work when these experiments were carried out.

This investigation was supported by Public Health Research Grant AM 07629 from the National Institute of Arthritis and Metabolic Diseases, U.S. Public Health Service.

We thank Mr. Gideon Einav for constructing the apparatus.

ENTOMOLOGY

An Inhibitory Effect of Allatectomized Males and Females on the Sexual Maturation of Young Male Adults of *Schistocerca gregaria* (Forsk.) (Orthoptera: Acrididae)

As shown by Loher¹, removal of the corpora allata from immature adult males of the desert locust (*Schistocerca gregaria* Forsk.) prevents the onset of sexual maturity and also the production of the pheromone which has an accelerating effect on the maturation of young males.

An investigation has recently been made into the relative effects of allatectomy and of severing the nervous connexions of the corpora allata on sexual behaviour, oocyte development and pheromone production in adult desert locusts². In the course of these experiments it became apparent that allatectomized males not only fail to accelerate maturation but actually retard it.

In one experiment, 19 young males were placed in separate jars within 24 h after fledging. Seven of them were kept each with one allatectomized male. The other twelve were kept each with a normal female of its own age. The allatectomized males were about four weeks old at the beginning of the experiment and had been operated on a few days after fledging—well before sexual maturation. The age at which the young males began to develop the yellow coloration on the abdomen (which is indicative of the onset of maturity³) was recorded. As soon as this point was reached, or earlier in the case of the last ones to become mature, the young males were put each with one fully mature female for about 5 h daily during which time they were kept under observation and their ages at first copulation or attempted copulation were noted. Those young males which were being kept with females were left with their own female during this period provided that she was fully mature; otherwise a fully mature female was substituted. At the end of each observation period, the young males were replaced with their usual partners. The males kept with allatectomized males started to become yellow in an average of 24.3 ± 9.4 days and first copulated, or tried to copulate, in an average of 29.5 ± 11.4 days. The males kept with females started to become yellow in an average of 17.0 ± 3.7 days and copulated, or tried to copulate, in an average of 19.2 ± 4.7 days. The difference in ages at copulation was significant ($P < 0.02$) and the difference in yellowing-times was also significant ($P < 0.05$). Of the males kept with allatectomized males the last one to copulate failed to become yellow and could not therefore be included in the calculation for yellowing-time. This accounts for the greater time elapsing between the average yellowing-time and the average copulation-time in this treatment.

The number of males kept with allatectomized males in the above experiment was small, so a larger experiment was next carried out in which young males were kept in four different ways as follows:

- | | |
|--|--|
| (A) Each with one allatectomized male | } allatectomized locusts operated on as in the previous experiment |
| (B) Each with one allatectomized female | |
| (C) Each with one normal female of the same age as the young males | |
| (D) Each in isolation | |

The results of this experiment are summarized in Table 1.

It is apparent that allatectomized males and allatectomized females have a similar retarding effect on male maturation and that the normal females are neutral in effect.

In a subsequent experiment the effect of the presence of allatectomized females on oocyte development in young adult females was investigated. Sixteen young females were kept in pairs with each other, another sixteen were

Table 1. EFFECT OF THE PRESENCE OF ALLATECTOMIZED MALES, ALLATECTOMIZED FEMALES AND NORMAL FEMALES ON THE MATURATION-RATE OF YOUNG MALE ADULTS OF *Schistocerca gregaria*

Figures represent average \pm S.D. in days after fledging. (In parentheses number of young males investigated)

Each young male kept:	First appearance of yellow coloration	First copulation
(A) With one allatectomized male	24.1 ± 6.9 (13)	27.7 ± 7.7 (13)
(B) With one allatectomized female	25.1 ± 6.7 (12)	26.5 ± 6.3 (12)
(C) With one normal female	18.6 ± 4.0 (12)	20.9 ± 4.2 (12)
(D) In isolation	17.5 ± 3.8 (13)	18.7 ± 3.5 (13)
Significance tests (P)	A/B not sig. A/C < 0.05 A/D < 0.01 B/C < 0.01 B/D < 0.01 C/D not sig. A + B/C + D < 0.001	A/B not sig. A/C < 0.02 A/D < 0.001 B/C < 0.02 B/D < 0.001 C/D not sig. A + B/C + D < 0.001

kept each with one allatectomized female, and another sixteen were kept each in isolation. When dissected at the age of 3 weeks the average lengths of the first or largest oocyte were respectively 4.4, 4.2 and 4.2 mm. The result was therefore negative, no effect of the allatectomized females being demonstrated.

It has previously been shown^{3,4} that, although the presence of mature males of *Schistocerca* has an accelerating effect on maturation, very young adult locusts within a week of fledging have the reverse effect and retard maturation of young males. The retarding influence of the allatectomized locusts is similar to that of very young locusts and it seems that allatectomy, as well as preventing maturation, prolongs the period during which an inhibitory influence on the maturation of others is exerted.

VIROLOGY

Nuclear Surface N-Acetyl Neuraminic Acid Terminating Receptors for Myxovirus Attachment

INSIGHT into the molecular organization of cellular membranes may be gained by defining their molecular components in terms of functional groups which serve as receptors for virus attachment. Thus, the specific attachment of myxovirus to neuraminic acid-terminating glycoprotein groups on the cell surface and the loss of virus binding capacity following exposure of cells to neuraminidase serve to define the neuraminic acid molecule in its role as a functional receptor on the plasma membrane¹. This report describes the first use of this approach to map the surface of nuclei by comparing the characteristics of myxovirus attachment and elution of whole cells with isolated nuclei. Here we demonstrate that the surface of cytoplasm-free nuclei prepared by treating cells with an anionic detergent contains specific receptors for the attachment of myxovirus, and that in terms of virus adsorption and elution the surface of nuclei isolated from HeLa cells reacts much like that of an erythrocyte, or of a host cell the viral engulfment capacity of which has been destroyed by heat.

Isolated nuclei are prepared by suspending monolayer dispersed HeLa S3 cells to a density of 2×10^6 cells/ml. in a cold 0.01 per cent aqueous solution of purified sodium dodecyl sulphate (SDS)². The cold SDS-cell suspension is pipetted 3–6 times through a 10-ml. pipette or mixed vigorously for about 30 sec on a 'Vortex-Junior' mixer. This brief treatment produces complete dissolution of the

asma membrane and most intracytoplasmic structures, and results in a quantitative yield of nuclei. This technique is similar in principle to several methods described recently³⁻⁶, but simpler in practice. The nuclei used in these experiments were washed with a K^+ -free phosphate-buffered-saline by centrifugation at 1,600 r.p.m. for 1 min in an International Model PR-2, and resuspended in attachment solution⁷ or K^+ -free saline. Nuclei were removed for adhering cytoplasm by means of oil immersion phase-contrast and dark-field optics, and with fluorescent microscopy of acridine orange-stained unfixed material under conditions known to reveal cytoplasm as brilliant red-orange fluorescence⁸. By these tests, more than 99 per cent of the nuclei were judged completely free of adhering cytoplasm and presented an extremely uniform and smooth appearance at the membrane-fluid interface. Electron microscopic investigations are underway to determine whether the surface of nuclei isolated in this manner consists of a single or double unit membrane⁹.

Virus attachment studies on isolated nuclei exposed to Newcastle disease virus (NDV), a representative of the myxovirus group the members of which characteristically bind to receptors terminating in *N*-acetyl neuraminic acid^{9,10}, are carried out as follows at 2° C: nuclei and cells are suspended in cold attachment solution to equal densities, usually 2.0×10^7 /ml., and an equal number of plaque-forming particles (PFU) of NDV are added to each of the two suspensions. Aliquots of the virus-cell and virus-nucleus mixtures are removed at various intervals, immediately diluted 1:20 in cold attachment solution, and centrifuged to remove cells, nuclei and bound virus. The supernatant fluid is assayed for unattached plaque-forming particles as previously described¹¹. Fig. 1 represents the characteristic attachment of NDV to HeLa cells and the loss of virus binding following the treatment of the cells with neuraminidase. Fig. 2 demonstrates that NDV binds equally efficiently to isolated nuclei, and that, as with whole cells, binding capacity is lost following incubation with neuraminidase. Values of the velocity constants for attachment¹², k , of NDV to whole cells and nuclei were experimentally equi-

Fig. 1. Newcastle disease virus attachment to neuraminidase-treated and non-treated HeLa cells. Temperature of attachment = 2° C

Fig. 2. Newcastle disease virus attachment to neuraminidase-treated and non-treated nuclei derived from neuraminidase-treated and non-treated HeLa cells. Temperature of attachment = 2° C

valent, with $k = 2 \times 10^{-9}$ cm³ min⁻¹. The patterns of NDV attachment to nuclei and cells were similar, that is, attachment was rapid and uniform for about 85 per cent of the virus population, and for the remainder slowed markedly to about one-tenth of the original rate.

When NDV at the low multiplicities (virus/cell ratio ≈ 1) used here is attached to HeLa cells at 2° C less than 0.2 per cent of the virus elutes when the temperature of the virus-cell complex is raised to 37° C (ref. 13), and within 10 min essentially all of the particles are engulfed by the cell¹⁴. In contrast, when virus-nuclei complexes formed at 2° C are incubated at 37° C virus elution commences, and within 30 min all initially bound virus is recoverable in the supernatant fluid as free plaque-forming particles (Fig. 3). This elution is accompanied by receptor destruction, and a consequent inability of the nuclei to bind virus as evidenced by a ten-fold reduction in uptake of a second virus input. Similarly, viral elution from the host cell surface may be demonstrated if engulfment of virus is prevented by heating the cells for 15 min at 50° C prior to virus attachment. Then, viral elution occurs at essentially the same rate as from the surface of isolated nuclei or bovine red blood cells, the latter used to verify the well-documented elution characteristics of myxovirus from erythrocytes (Fig. 3).

To test whether receptors for attachment of myxovirus to the surface of nuclei are artefacts, derived from the cell membrane during the isolation procedure, the following experiment was performed: HeLa cells were treated with neuraminidase (Grand Island Biological Co., New York) for 15 min at 37° C to remove all cell surface-situated receptors as tested by: (a) release of *N*-acetyl neuraminic acid (NANA) determined chemically¹⁵; (b) loss of virus binding capacity; or (c) loss of cell susceptibility to infection¹⁶; then cooled to 2° C, washed, and treated with SDS to obtain nuclei. The curve labelled 'neuraminidase-cells → nuclei' in Fig. 2 demonstrates that under these conditions complete removal of receptor *N*-acetyl neuraminic acid molecules located in the cell membrane has no effect on the receptor complement of subsequently isolated nuclei as judged by the rate of NDV attachment.

Fig. 3. Newcastle disease virus elution at 37° C from HeLa cells heated for 15 min at 50° C, nuclei derived from HeLa cells, and bovine erythrocytes. Virus attachment initially at 2° C for 30 min

We were concerned with the relative amounts of sialic acid on the surface of whole cells and nuclei isolated from them, and hence determined the amount of neuraminic acid freed from these two surfaces following treatment with neuraminidase (15–25 units enzyme/ 1×10^7 cells or nuclei for 20 min at 37° C in phosphate-buffered-saline containing 10^{-3} M Ca^{++} ; conditions adequate to release maximal amounts of sialic acid as assayed by the Warren procedure¹⁵). Table 1 lists the sialic acid (NANA) content of HeLa S3 cell and nuclear surfaces as the average and standard deviation of from 5 to 10 determinations made on cells, or nuclei from cells, grown in spinner culture. To determine whether the low NANA content of the nuclear surface was due to removal of membrane bound-NANA moieties by SDS, we tested the sensitivity of plasma membrane-bound NANA to removal by the detergent, since the normal content of NANA on the cell surface was known (Table 1). Sialic acid freed from the cell surface by neuraminidase was measured after exposing the cells to SDS under conditions that do not produce dissolution of the plasma membrane, namely, 0.01 per cent SDS in cold isotonic K^+ -free saline. Cells exposed in this manner, first to SDS, release the usual amount of NANA ($0.16 \mu\text{M}/1 \times 10^8$ cells) after enzyme treatment, indicating that our standard treatment with detergent apparently does not free NANA-containing molecules from membrane.

In light of the equivalent velocity constants for NDV attachment to nuclear and cell surfaces, and hence the presumed equivalent collision efficiency of the two systems, the 24-fold excess of neuraminic acid groups on the cell surface revealed in Table 1 presents somewhat of an anomaly, and suggests that many of the NANA prosthetic groups are not functional in a receptor capacity (perhaps inaccessible as Burnet¹⁶ has thought in accounting for the receptor gradient), a concept consistent with the fact that only a small fraction of plasma membrane-located carboxyl groups of NANA may effectively contribute to the net negative charge on the cell surface¹⁷. On the other hand, when the contribution of microvilli to the cell surface is considered, the surface area per cell

approximates $10^4 \mu^2$, or about 10^5 molecules of NANA per μ^2 . With the surface area of the nucleus estimated at about $500 \mu^2$, there are also about 10^5 molecules of NANA per μ^2 . The errors inherent in evaluating the total cell and nuclear surface areas are of such magnitude that the density of NANA molecules on each surface might, as a first approximation, be considered equal. The equivalent k values obtained for the attachment constants are thought to support this view.

During the sialic acid determination we noted that nuclei treated with neuraminidase to release surface NANA did not leak significant amounts of 2-deoxyribose as measured spectrophotometrically¹⁸, attesting to the integrity of the membrane of isolated nuclei, since rupture of the nuclear membrane by sonication or acid hydrolysis was shown to release large amounts of this sugar. In the connexion, the relative stability of the nuclear membrane of mammalian cells in hypotonic solutions of detergent of general interest. For the preparation of cytoplasm-free nuclei, the concentration of cells suspended in aqueous SDS is critical. As higher densities of cells are used, correspondingly larger fraction of nuclei is found with cytoplasmic debris adhering to their periphery; noticeably, the Golgi-region of the cytoplasm is most tenaciously bound, and hence invariably the last portion of the cytoplasm to fall free.

Throughout these investigations we have been impressed with the specificity and sensitivity of the biological test system, viral attachment, over that of the chemical reactions used to detect NANA-terminal groups. For example, it was necessary to amass more than 10^6 nuclei for a single chemical determination, whereas 10^4 nuclei suffice to detect receptors, or the loss of same, by viral attachment techniques.

These investigations demonstrate that viral attachment to particular molecular groups on the surface of cell or nuclei can be used as a biological approach of exquisite specificity and sensitivity to define the complex mosaic of chemical entities that constitute the functional group of cytomembranes. To pursue this approach further we have initiated a complementary investigation designed to determine the rate and pattern of reappearance, and conditions governing the replacement of NANA terminating groups on the surface of normal individual cells¹⁹.

This work was aided by grant AI-03619-05 from the U.S. National Institutes of Health. One of us (P. I. M.) is a research career development awardee of the National Institute of Allergy and Infectious Disease, U.S. Public Health Service (2-K3-GM-15, 461-05).

Effect of β -Propiolactone and Thiomersal on Growth of B.H.K. Cells in the Hamster Cheek Pouch

THE use of tissue cultures of continuous cell-lines for preparing vaccines poses a number of problems which are assumed not to exist when primary cell-cultures are used. Undoubtedly the most interesting aspect requiring clarification is the potential of these cells to multiply when inoculated into an animal. There are several factors which could have a bearing on this, in particular the physical treatment that the cells undergo during the preparation of a vaccine. This treatment is probably most severe in the preparation of inactivated vaccines, and we have examined the various stages of this process to determine their effect.

Newcastle disease vaccine can be prepared by growing the virus in tissue culture, inactivating with 1:1,000 β -propiolactone and afterwards adding 0.013 per cent thiomersal as a preservative. Virus, inactivating agent and preservative are each capable of causing cell damage and were therefore investigated. The test involved virus growth in cells derived from the B.H.K. 21 cell line which had been previously modified until they were capable of growing in suspended culture. Inoculating the hamster cheek pouch was used for detecting the presence of viable cells. This system could also detect oncogenic substances that might be released from the treated cells.

A suspension of B.H.K. cells in the log phase of growth, with a viable count of 1.5×10^6 cells/ml., was concentrated by centrifuging at 166*g* for 15 min. The cells were immediately resuspended in maintenance medium at concentrations of 10×10^6 , 20×10^6 and 30×10^6 cells/ml. Each of these suspensions was divided into three portions, one being treated with β -propiolactone, one with thiomersal and one left untreated.

Treatment with β -propiolactone was carried out by adding a freshly prepared 10 per cent solution of β -propiolactone in distilled water to the cell suspension to give a final concentration of 1:1,000; the mixture was then kept at 37°C for 2 h, and after adjustment of the pH to 7.2 it was inoculated into hamsters. A further sample was treated with thiomersal at a final concentration of 0.013 per cent by adding it to cells maintained at +4°C. This mixture was inoculated into hamsters after treatment for 2 h. The control cells received no treatment apart from storage at +4°C for 2 h before inoculation.

Syrian hamsters weighing 50–60 g were used. The technique adopted was that described by Handler and Foley¹, except that the animals were anaesthetized with ether before inoculation and when they were examined for signs of tumour development. 0.1 ml. of a suspension of cells was implanted under the epithelium of the cheek pouch with a 26-gauge needle. Only one cheek pouch was inoculated. Each cell suspension was given to a group of four hamsters; two of them received 0.1 ml. cortisone solution ('Cortelan' 25 mg/ml.) subcutaneously at the time of inoculation. This dose was repeated three times a week for 3 weeks. The hamsters were observed daily during the first week and three times a week thereafter.

Small nodules, approximately 1 mm in size, were evident in most hamsters during the first few days after inoculation. These nodules either regressed or became visibly larger, depending on the type of cell suspension administered. In certain instances the nodules were associated with a prominent vascularity. When a nodule developed, the hamster was retained until the nodule became large or showed signs of breaking down. The nodule was then excised for histological examination. Transplantations of nodules to other cheek pouches were not made. In those hamsters in which nodules failed to develop, the animals were retained for 42 days before being killed, and the area of the cheek pouch that had been inoculated was removed for histological study.

When untreated B.H.K. cells were inoculated at the three different cell concentrations, the initial nodules enlarged considerably from the seventh day onward and became markedly vascular by the tenth day. No apparent difference was noticeable between the pairs of hamsters receiving cortisone and the others. The hamsters were retained for 14–24 days before the nodules were excised. Histological examination of the nodules revealed extensive cellular proliferation. The pattern was that of an undifferentiated cell sarcoma; numerous mitotic figures were present and there were signs of tissue necrosis in the central area. The interpretation was that cells in the inoculum could proliferate in the hamster cheek pouch and produce tumours similar to those we have seen in earlier studies with HeLa cells.

B.H.K. cells treated with thiomersal at the two higher cell concentrations produced nodules with an associated vascularity in the cheek pouches. Hamsters inoculated with the smallest concentrations of thiomersal-treated B.H.K. cells, 10×10^6 cells/ml., developed no nodules during 42 days' observation. The histological sections on the cheek pouches of these animals revealed no abnormalities except occasional local inflammatory responses.

B.H.K. cells treated with β -propiolactone produced no nodules in hamsters at any of the three concentrations of cells. Histological sections of cheek pouches were normal, apart from minimal inflammatory responses in some sections.

An attempt was made to assess the effect of Newcastle disease virus on the viability of B.H.K. cells. Unfortunately this had to be combined with inactivation by β -propiolactone in order to avoid the presence of live virus in the animal house. A suspension of cells with a viable count of 2×10^6 per ml. was infected with a tissue-culture adapted strain of Newcastle disease virus. Four days later the cells were removed and concentrated by centrifuging; they were then resuspended in supernatant to give a final cell concentration of 30×10^6 per ml. Inactivation with 1:1,000 β -propiolactone was carried out as previously described. The sample was divided into halves; one received no further treatment, but thiomersal was added to the other at a final concentration of 0.013 per cent. None of the inoculated hamsters developed tumours, and there was no histological sign of cell proliferation.

It would seem that β -propiolactone at a concentration of 1:1,000 is highly efficient for preventing subsequent multiplication of the cells. Thiomersal at a concentration of 0.013 per cent appears to have a marginal effect during the short period of treatment used. The fact that it was able to inhibit cell growth when low concentrations of cells were used may be related to the lower protein content of this particular cell suspension; with higher cell concentrations non-specific absorption of the substance may occur, reducing its availability. Alternatively, the initial low concentrations of the preservative or the short treatment may be responsible for lack of inhibition at higher cell concentrations. In practice the cell concentration of a vaccine is likely to be less than one-fifth of the lowest concentrations we used, and at these levels 0.013 per cent thiomersal totally inhibits cell growth.

Table 1

Cell suspension	Cells per 10 ml.	Regression (R) or progression (P)	Vascularization	Host inflam. response	Mitosis. Few or none — Many +
B.H.K. alone	30×10^6	P	Marked	—	+
	20×10^6	P	Marked	—	+
	10×10^6	P	Marked	—	+
B.H.K. + thiomersal	30×10^6	P	Marked	—	+
	20×10^6	P	Marked	—	+
	10×10^6	R	Poor	+	—
B.H.K. + β -propiolactone	30×10^6	R	Poor	+	—
	20×10^6	R	Poor	+	—
	10×10^6	R	Poor	+	—
B.H.K. + NDV virus + β -propiolactone	No thiomersal	R	Poor	+	—
	Thiomersal	R	Poor	+	—

Under the conditions of these experiments, the physical treatment that a virus vaccine undergoes during the various production stages of virus growth, inactivation and addition of preservative, was shown to be deleterious to the tissue culture cells from which the virus was produced; using a highly sensitive test system we were unable to demonstrate surviving cells. We were unable to demonstrate any breakdown product capable of producing tumours.

From these experiments it seems that the preparation of an inactivated vaccine from virus grown in these cells would carry no risk of inducing malignant tumour growth in hamsters and hence would also carry no risk for a heterologous host, in which there would, moreover, be an immunological barrier.

GENETICS

Linkage in Man: the Inv and the Lp Serum Type Systems

THE new serum type system Lp¹ is a useful genetic marker system, the frequency of the Lp^a gene being approximately 0.18 in Caucasians^{2,3} and test reagents unrestrictedly available. Concerning the serum type system Inv (refs. 4 and 5), test reagents have been relatively difficult to obtain, but are now increasingly available³⁻⁵. The established Inv^a or Inv^{1a} gene frequencies, 0.06-0.10 in Caucasians and considerably higher in other populations, would indicate common use of this marker system in the future. This pre-supposes the elucidation of the genetics of this system, including analysis of linkage relationships. This communication provides data on the Inv-Lp linkage relation.

The material comprised 87 unrelated parents and 20 children from Norwegian families tested for Lp(a) and Inv(a). Of the unrelated individuals 67 were derived from a family material considered earlier as regards Lp(a) by Mohr and Berg², and 20 derived from a material concerning *Epidermolysis bullosa* (Gedde-Dahl, in preparation).

Anti-Inv(a) Math. serum and anti-D Roehm serum were kindly provided by Dr. A. G. Steinberg, while anti-Lp(a) serum was of our own production (K. B.). The Inv typing was performed as outlined by Steinberg⁵ with minor modifications, and the Lp typing as described by Berg².

Among the 87 unrelated individuals 13.79 per cent (12 individuals) were found to be Inv(a⁺) and 33.33 per cent (29 individuals) Lp(a⁺) (Table 1). Four matings of the type Inv(a⁺)Lp(a⁺) × Inv(a⁻)Lp(a⁻) were observed among the 40 pairs of parents where both parents were tested. As appears from Table 2, recombination between the Inv and Lp loci must have taken place in each of these families. The Fisher-Finney method¹⁰ gave values of 73.225 units, a linkage score of -7.233 and a test value of -0.845. The most likely recombination frequency is 50 per cent, that is free recombination. By the Morton-Smith method¹¹, linkage between the Lp and Inv loci may be excluded with a probability of 0.985, and linkage below 30 per cent with a probability of 0.996. It may be noted that practically all the information, 66 units by the

Fisher-Finney method, was derived from a single 12 s family. In all four families the double heterozygote parent was the mother.

Berg and Mohr¹² found the phenotype Lp(a⁺) in 34.6 per cent of 314 unrelated Norwegians. 67 of these, namely 23 Lp(a⁺) and 44 Lp(a⁻) individuals, are included in the present material. The frequency of the phenotype Inv(a⁻) has not previously been estimated for the Norwegian population. The distribution in the present material however, does not differ significantly from our own finding of 14 Inv(a⁺) individuals among 143 Norwegians not included here ($\chi^2: 0.86, 0.5 > P > 0.3$). Both materials combined gave a phenotype frequency of Inv(a⁻) of 11.2 per cent. These results of Inv(a) will be included in later publication.

From the gene frequencies of Lp^a 0.1877² and Inv 0.059 an expected number of 0.8 double backcross matings among 40 random Norwegian matings may be calculated. Actually, 2 such matings were observed among 33 from a unselected family material, and 2 out of 7 in families selected by *Epidermolysis bullosa* and by the number of children.

It appears that the linkage relations of the Inv loci have not previously been analysed beyond an exclusion of linkage closer than 30 per cent recombination between the Inv and Gm loci¹³.

Work on the relations between the Lp locus and the loci of the ABO, MNS, Rh, Le, Lu, P, Fy, Jk, K, Hp, G, Gm, and Ag systems has not revealed any linkage, but information on some of the relations was scarce^{2,9}.

The calculations were made by Mr. Dan Wøien, of the University Institute of Mathematics, Oslo, by means of an IBM electronic computer 1620 II.

Artificial Insemination of Dystrophic Mice with Mixtures of Spermatozoa

MUSCULAR dystrophy in mice (*Dystrophia muscularis* symbol *dy*) is transmitted as an autosomal recessive and is linked to Steel (*Sl*) and Ames waltzer (*av*) in linkage group IV³⁻⁵. Mice of genotype *dy/dy* have pronounced weakness of the hind limbs and die as young adult. Dystrophic male mice do not breed, and dystrophic females may have one or sometimes two litters early in their reproductive life, when mated to normal male. The disease can be recognized in mice 2-3 weeks old and has a characteristic manifestation, described in detail by Michelson *et al.*¹ and Loosli *et al.*².

In a previous report⁷, litters consisting entirely of dystrophic (*dy/dy*) mice were obtained by inseminating dystrophic *F*₁ hybrid females (*F*₁ hybrid from 12 *Re-dy/+* × *C57BL/6-dy/+*) (ref. 8) with spermatozoa from *F*₁ hybrid males of the same genotype. The number of dystrophic females producing litters following artificial insemination approaches that observed with natural

matings of hormonally primed 129B6F₁ normal females (Table 1). The offspring are homozygous for dystrophy (dy/dy) but are otherwise a genetically segregating population. Variation in genetic background does not, however, cause any appreciable differences in the expression of dy/dy genotype^{6,10}.

This communication reports reproductive performance of dystrophic females following insemination with mixtures of genetically-tagged spermatozoa, along with information on genotypes of offspring. The eye-colour markers, pink-eyed dilution (p) and its wild-type allele (+), were used to identify normal and potentially dystrophic individuals from 12 days of gestation forward. This method permits within-litter biochemical and histopathological comparisons of dy/dy and dy/+ muscle in pre-clinical stages.

All mice used in these experiments were 129B6F₁ hybrids, but special mutant-carrying sub-lines of strains 129 and C57BL/6 were required to provide the desired colour markers. A mutation at the pink-eyed dilution locus (p^m) in the C57BL/6 strain permitted the development of a C57BL/6-p^m dy strain from the existing C57BL/6-dy strain, the latter described by Russell *et al.*⁸. A 129/Sv-CP sub-strain homozygous for the wild-type alleles of pink-eyed dilution and dystrophy (N10) was available through the courtesy of Dr. Leroy Stevens.

Ovulation was hormonally induced in all females by intraperitoneal injections of 2 i.u. of pregnant mare serum (PMS) (Ayerst Laboratories, Inc., New York) followed in 36–40 h by 2 i.u. of human chorionic gonadotropin (HCG) (Ayerst Laboratories, Inc., New York). In production of all dystrophic litters, spermatozoa from the ductus deferens and epididymis of one 129B6F₁-dy/dy male, suspended in 0.4 ml. 0.85 per cent sodium chloride at room temperature, were sufficient to inseminate approximately five 129B6F₁-dy/dy females. In production of mixed dystrophic-normal litters, spermatozoa from a mature pink-eyed dy/dy male and from a dark-eyed +/+ male of comparable age were suspended together in 0.8 ml. saline. Each female received 0.04–0.05 ml. of the spermatozoa through the cervix (method of Dziuk and Runner, 1960) (ref. 9), 10–12 h after injection of HCG. Immediately following insemination each female was put with a vasectomized male until a vaginal plug was observed. The mean age of all females was 55 days, range 32–89 days. Dystrophic females frequently do not withstand the strains of pregnancy and lactation, hence it was often necessary to take their litters by Caesarean section at the 19th or 20th day of gestation. Pregnant

normal females, which had been primed and mated 2 days prior to the artificial insemination of the dystrophic females, were used as foster-mothers for these litters.

When spermatozoa were mixed from two males, one of genotype p^m/p dy/dy and the other of genotype +/+ +/+, and then inseminated into females of genotype p^m/p dy/dy, approximately equal numbers of pink-eyed offspring (230) and dark-eyed offspring (220) resulted (Table 2). However, in any single experimental group the proportion of pink-eyed and dark-eyed offspring often deviated markedly from the expected 1:1 ratio. The pink-eyed offspring were presumed to be dystrophic whereas dark-eyed offspring were presumed to be normal heterozygous carriers of dystrophy. The majority of the potentially dystrophic young were used in various pre-clinical studies and thus could not be checked for expression of dystrophy. These results suggest equal transmission and fertilizing ability of p dy and p^m dy spermatozoa compared with +/+ spermatozoa. Extensive counts (unpublished) from dystrophic and normal F₁ hybrid males have shown no significant differences in numbers of spermatozoa.

We thank Mrs. Ada Grindle for her technical assistance.

PSYCHOLOGY

Shift Working: the Arrangement of Hours on Night Work

PROBLEMS of adaptation to shift-working routines may be increased by physiological disturbance when changing to night work is involved. It has been shown that performance on some kinds of work can be affected by inversion of normal time routines so that output at night is lowest in the early hours of the morning^{1,2}. This is believed to be associated with diurnal rhythms which persist with old periodicities into the new routines. Experiments have shown, however, that complete inversion of the environment is accompanied after a period by synchronization of diurnal rhythms with the new routines³. For this reason physiologists have sometimes suggested that, to facilitate adaptation and improve efficiency, night work should be permanent or for a long period^{4,5}.

While this recommendation may be suitable for special occupational groups it fails to take into account many variables in the industrial situation. Social, domestic and recreational interests also have their place in the shift-worker's life, and these make it impossible to live in a completely inverted environment. In these circumstances adaptation of the diurnal rhythms becomes less probable and there is some evidence that it does not occur. Van Loon⁶ has shown that the temperature periodicity of three men, although modified, failed to invert after 13 weeks on night shift when continuity was inter-

* 6 a.m., 2 p.m., 10 p.m.

rupted by a weekly rest-day. Studies by Wyatt and Marriott⁷ of absence from work and work performance of shift-workers, both on a fortnightly and on a monthly cycle, showed an increase in absence during successive weeks of the night shift and a decrease in absence and an increase in output in the following weeks of the day shift. Although not based on physiological measures, this suggests a failure of adaptation and a consequent accumulation of fatigue over the period of the night shift which was dissipated on the subsequent weeks of the day shift. Finally, night workers appear to retain some day-time eating habits, and if times of food intake are a secondary synchronizing factor⁸ this will interfere with adaptation.

Two studies have been carried out of the behaviour and preferences of men engaged on shift work. In the first, chemical workers in a large plant had been operating a continuous shift system, in which they worked seven shifts followed by a rest period, before changing to a different shift. On the insistence of the men and after balloting, the system was changed to a 3 × 2 × 2 cycle (Table 1). This type of cycle results in short but frequent bursts on the night shift. Interviews with a sample of fifty men, after three years experience of the new cycle, showed that all but seven men preferred the shorter cycle. The main reasons given for this preference were that they felt less tired and that they had more opportunity for participating in normal social and domestic life each week. Of those preferring the longer cycle, only four gave a reason which indicated some degree of physical adaptation during the seven-shift cycle.

The second study⁹ examined the behaviour of men on shift work who were allowed to exchange shifts among themselves. They could also ask to be placed on a permanent night list. The men worked a variety of shifts arranged in a complex 32-week rota in which night duties were listed for two in every seven or eight weeks. The study showed that one in five of all listed duties were exchanged and that 87 per cent of these changes were between day and night duties. The original rota was planned so that each man worked 25-35 per cent of his time on night duty. As a result of the exchanges and of permanent night-duty listings the numbers of men working different proportions of night duty were distributed as shown in Fig. 1. The bimodal distribution indicates preference for either permanent day- or permanent night-working. That this preference is associated with adapta-

Fig. 1 Distribution of population according to percentage of working time spent on night shift

tion of diurnal rhythms, however, is doubtful. The night duty worked was one of alternate nights—one night on and one night off—and adaptation to a 48-h cycle has not, up to now, been demonstrated⁴. In addition, the 48-h cycle was broken by the fairly frequent interpolation of overtime nights. A more detailed study of the population is planned.

The variety of behaviour observed in these investigations suggests that adaptation to shift working is a complex process involving the balancing of many factors in both the internal and external environment. For this reason no single solution to the problem of the best arrangement of shift cycles is likely to be generally applicable. An extension of shift work and night work is anticipated and with shortened weekly hours there will be greater flexibility in their arrangement. Before theories of the optimum arrangement of shifts are formulated more must be known of the nature and interaction of psychological and social, as well as physiological, factors in the working situation.

Effect of Infantile Treadmill Experience on Body-weight and Resistance to Exhaustion in the Rat

AN earlier experiment reported an inverse relationship between the age of rats and their exhaustion time on a slowly and continuously revolving wheel¹. The experiment reported here show the effect of early treadmill experience on later resistance to exhaustion and a hitherto-unnoticed weight-gain effect.

The apparatus used in these experiments was similar to that used previously¹⁻³. The rats were placed in individual 5.5 m. by 9.5 in. cubicles, on wheels two-third submerged in water and constantly rotating at 2 r.p.m. Each animal was in a separate compartment and food was available at all times.

The Ss in these investigations were male Long-Evan rats from the University of Florida colony.

In Exp. 1, eight Ss were placed on the wheel for 2 day at 40 days of age and 4 days at 60 days of age (the split period was inadvertently brought about by a wheel breakdown). A control group matched by litter and mean group body-weight was given no wheel experience. At 120 days of age both groups were placed on the wheel until exhaustion. The criterion for exhaustion was inability of the S to maintain himself on the wheel. The data from this and the second experiment are summarized in Table 1. The mean hours to exhaustion for the experimental and control animals were 82 and 67 respectively. In addition it was noted that at 120 days the experimental group weighed considerably more than the control group.

Table 1 BODY-WEIGHT AND EXHAUSTION TIME AS A PERCENTAGE CHANGE FROM CONTROL GROUP

	Body-weight before infantile experience	Body-weight after infantile experience	Body-weight before final exhaustion test	Exhaustion time
Exp. I	100%	86%	107%	122%
	40 days old	64 days old	120 days old	
Exp. II	101%	69%	114%	143%
	60 days old	68 days old	160 days old	

Fig. 1. Mean experimental group weight as a percentage of control group

Encouraged by these results—and intrigued by the gain in weight figures, six *Ss* were placed on the wheel at 50 days of age for 8 days. Six litter- and weight-matched controls were not given wheel experience. Weights were obtained prior to and immediately after the wheel experience and weekly thereafter.

At 160 days of age both groups of *Ss* were placed on the treadmill until exhausted. The mean hours to exhaustion were 70 and 49 for the experimental and control groups respectively. An analysis of variance of the exhaustion times for the combined data from Exps. I and II showed a significant difference between the experimental and control groups ($P < 0.001$); however, no significant experiment effect (Exp. I versus Exp. II) or interaction (between experiment and infantile experience) was found.

Fig. 1 presents the weight of the treated group in Exp. II as a percentage of the control group. It can be seen both in Fig. 1 and Table 1 that the infantile treadmill experience caused the experimental groups to fall behind the control *Ss* in weight and that, following the treatment, the experimental *Ss* caught up with and by-passed the control group.

Two possible interpretations of these results have been eliminated by further experiments. Animals starved to 72 per cent of a matched group weight at 50 days of age (taking about 48 h) caught up with the control group weight by 66 days of age and remained there with no increase above the control group weight (total $N = 14$). When both groups were placed on the wheel at 150 days of age no significant difference in resistance to exhaustion was present. Thus neither the weight gain nor the increased resistance to exhaustion can be attributed to infantile weight loss *per se*.

Another possibility was that the increased resistance to exhaustion of the treated *Ss* was mediated by their heavier weight. When normal *Ss* from another study³ were grouped so as to match same-aged litter-mates and compare the heavier with the lighter *Ss* as to resistance to exhaustion, it was found that at a given age lighter animals walked longer on the wheel ($t = 3.2$, $n = 16$, $P < 0.01$).

It appears that the treadmill acted as a stressor and that this 'acute stress' during infancy was responsible for the increased growth of muscle and other tissue. It is not known whether the improved treadmill performance is indicative of a general increased resistance to stress or is a specific effect of the early treadmill experience perhaps reflecting a 'learning' component.

This work was supported in part by a National Institutes of Health grant (NIH-MH-03881-03) to W. B. Webb and a National Aeronautics and Space Administration predoctoral fellowship (NASA-BSG (T)-13) to R. A. Levitt.

Form-similarity between Phosphenes of Adults and pre-School Children's Scribbles

We reported earlier^{1,2} a method which permits reproducible electrical stimulation of phosphenes—that is subjective light patterns, visible with closed eyes—without surgery. It was shown that these patterns resembled line drawings of 'geometrical' forms, and that a great number of them could be stimulated within a rather small bandwidth (± 10 per cent of the mean excitation frequency) within the electro-encephalographic frequency range. In the meantime, the dependence of this effect on the shape of the stimulating current³, the identification and lifetime of single phosphenes⁴ and the influence of hallucinogenic drugs on their shape⁵ have also been investigated. In addition, copies of 520 phosphenes observed by 313 subjects have been collected⁶: it was possible to classify these into 15 form groups ('phosphene-Linnaeus', 1-15, first two columns of Table 1).

As reported elsewhere⁷, a particular similarity was found between scribbles of young children and such phosphenes induced electrically in adults. According to about 300,000 drawings and paintings from pre-school children of American, Chinese, French, English and Negro origin, collected by one of us (E. K.) in the Golden Gate Nursery School, San Francisco⁷, it would seem that, at this age,

Table 1. OCCURRENCE OF 15 TYPICAL PHOSPHENE FORM GROUPS (COLUMN A, LIT. 3) IN 329 SCRIBBLES OF ONE SINGLE CHILD (CYNTHIA LIS, GOLDEN GATE NURSERY SCHOOL)

Percentage of scribbling form groups corresponding	100	60	80	60	80	86	86

Column A: Number of phosphenes belonging to each phosphene form group.

Columns B-G: Numbers of recognizable scribbles (out of 329) similar to each phosphene form group, according to 6 different experimenters.

such 'outlinings in geometrical style' play an important part in the development of a child's expression in drawing or painting.

The scribbling starts early (from an age of about two years); about twenty typical 'scribbles' and six typical 'diagrams' (Greek cross, square, circle, triangle, odd-shaped area and diagonal cross) have been observed (Fig. 1, below) and classified (ref. 7, pp. 131-132). From these basic geometrical forms ('scribbles' and 'diagrams'), the child later develops 'combines' and 'aggregates' (Fig. 1, middle) which each include two or more diagrams and enable him, from about an age of four years onwards, to compose more complicated representations of objects of his environment, such as Sun, people, houses, animals and flowers, from the basic geometrical outlinings (Fig. 1, above). If we compare the basic form groups of the Munich 'phosphene-Linnaeus' (first two columns on the left of Table 1), with those of the San Francisco 'scribbles-Linnaeus' (ref. 7, pp. 131-132) we see that nearly 90 per cent of the phosphene forms can be found in the 'scribbles-Linnaeus', although they were collected independently from each other. We note, for example, that they have the following figures in common: arcs, radials (crosses), waves, lines, combined patterns, circles, dots, odd figures, quadrangles, spirals, poles, triangles and 'cherries'. Lattices and fingers do not appear in the 'scribbles-Linnaeus' (ref. 7), but are scribbled occasionally.

An interesting question arises as to how many different basic form groups one particular child can produce by

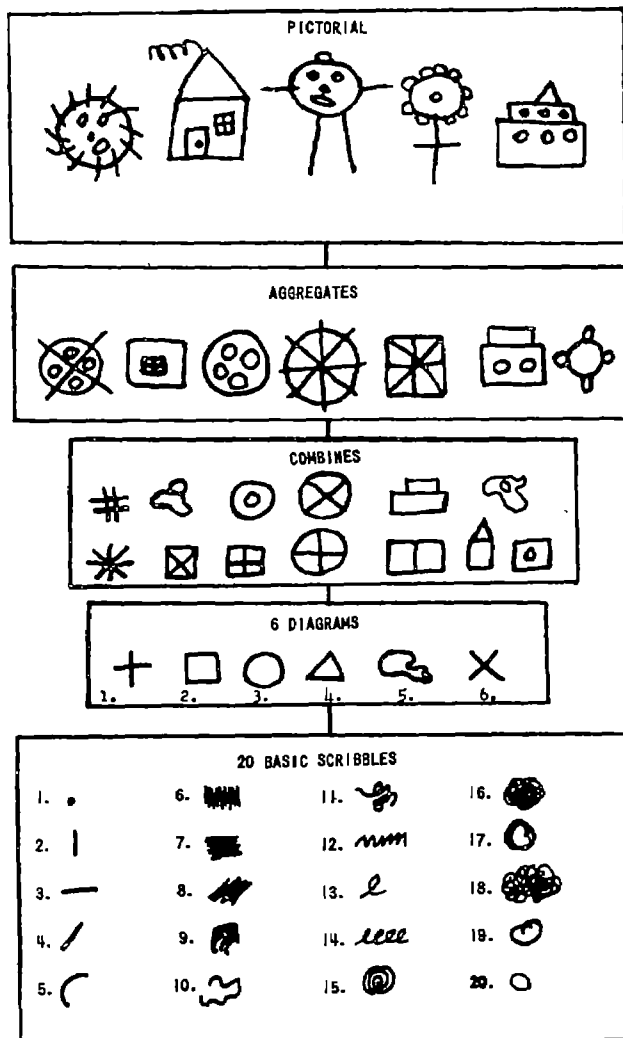

Fig. 1 Development of outlinings of 3-6-year-old children (ref. 7)

scribbling, as compared with the number of basic form groups of phosphenes in adults. Table 1 shows in its columns B-G (besides the classification of 520 electrically induced phosphenes of adults already discussed in A) the number of basic scribbles selected from 329 spontaneous outlinings of one single child (Cynthia Lis, 36-43 months old). The scribbles have been collected and checked by the Golden Gate Nursery School.

The selection of recognizable scribbles and the comparison with the phosphene form groups was made by six different adult experimenters: one of us (R. K.) found 9 such groups (Nos. 2, 3, 5-10, 12) in 124 basic patterns recognizable for her; another (M. K.), 12 groups in 114; the other (J. K.), 9 groups in 154. Our colleagues found E. L., 12 groups in 75; H. R., 13 groups in 167; W. G. 13 groups in 172. Each column B-G shows the number of basic scribbles corresponding to each phosphene form group in column A.

Although we are comparing here the phosphene patterns of 313 adults with the scribbles of only one child, it can be seen that a high proportion (60-86 per cent) of the child's 'eligible' patterns fits into one of the 13 form groups of the 'Phosphene Linnaeus'. To obtain significant statistical results it is, of course, desirable to analyse scribbles of a greater number of children as well as to increase the number of phosphenes in the Linnaeus further. It can be concluded, however, that the forms of phosphenes and children's scribbling have in common quite a number of elementary geometrical forms. (A similar relationship seems to exist between the form of phosphenes and the forms of certain Neolithic rock drawings (see ref. 6). The furnishing of comparative data for both relationships by the Werner Reimers Foundation for Anthropogenetic Research, Frankfurt, is gratefully acknowledged.)

This result may help to clarify the neurophysiological mechanism for the production of both phenomena, about which, so far, very little is known. As the behaviour of young children shows, the ability to scribble 'geometric patterns' does not exist in a child under the age of three. It seems to develop, however, starting from elementary motoric movements, rather rapidly (within months) as result of the very process of scribbling. At the end of this period, however, each child does not scribble an innumerable number of different patterns but only a limited number of 'basic' ones. From this one may conclude that we are dealing here with the activation of pre-formed neuronal networks in the visual system.

Certain networks in the visual system (neuronal oscillators or coincidence filters with small bandwidth within the electro-encephalographic frequency range) have been considered as a model for the phosphene phenomena^{5,8}. In case this or similar approaches confirm the experimental results, one can perhaps hope for a satisfactory general neurological clarification of the mechanism of pattern- or Gestalt-recognition.

For the comparison of phosphene patterns and scribbles we thank Dr. W. Grozinger, Mrs. E. Ledig and Prof. H. Richter.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, December 13

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m.—Mr. D. W. Trigg: "Logic of Stock Replenishment Subject to Production Constraints".

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. S. A. Mitchell: "The Surface Properties of Amorphous Silicas".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Annual General Meeting.

INSTITUTION OF MECHANICAL ENGINEERS, HYDRAULIC PLANT AND MACHINERY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Application of Control Theory to Control of Surges".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. L. Truquer—Presidential Address.

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 8 p.m.—Prof. P. E. Ireland (University of Toronto): "Preparation of Man for Travel into Space".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Dr. R. B. Sarjeant: "Background to the Yemen War".

Tuesday, December 14

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Mr. D. A. Mackintosh: "Automation"; 4.15 p.m.—Mr. I. C. Heatham: "Rolling Ball Loss Spectrometer".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Meeting on "Forth Road Bridge".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATIVE DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. J. Ray: "Hot-Strip-Mill Adaptive Computer Control".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. H. Cooke-Yarborough: "Recent Developments in Nuclear Instrumentation".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 12, House of Commons, Westminster, London, S.W.1), at 3.30 p.m.—Discussion on "Water Resources" initiated by Mr. N. A. F. Rowntree and Prof. Jansen (University of Delft).

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. P. Shillingford: "Cardio-pulmonary Function Following Myocardial Infarction". (Fourteenth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation)*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. B. J. Albert and Mr. J. C. Walker: "Tyre to Wet Road Friction and High Speeds".

Tuesday, December 14—Wednesday, December 15

INSTITUTE OF METALS (at the Royal Commonwealth Society, Craven Street, London, W.C.2)—Inaugural Meeting of the Joint Committee on Heat Treatment, including discussions on: (a) Scientific Aspects, (b) Heat-Transfer Practice, and (c) Equipment.

Wednesday, December 15

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Dr. F. V. Flynn: "Data Processing and Computers in Clinical Pathology".*

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. D. R. Grant: "Some Aspects of Convection as Measured from Aircraft"; Mr. S. D. R. Wilson: "Instability of a Geostrophic Wind with a Transverse Wind-speed Gradient"; Mr. G. O'Mahoney: "Rainfall and Moon Phase".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. B. P. Emmett: "The Design of Investigations into the Effects of Radio and Television Programmes and other Mass Communications".

INSTITUTE OF FUEL (at the Royal Institute of British Architects, 66 Portland Place, London, W.1), at 5.30 p.m.—Dr. P. J. Foster: "Carbon in Flames".

INSTITUTE OF MATHEMATICS AND ITS APPLICATIONS (in the Large Physics Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. M. F. Atiyah, F.R.S.: "Global Aspects of Elliptic Differential Equations".*

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. K. K. Schwarz: "Further Developments in the Design and Performance of High-Voltage Terminal Boxes".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. E. J. Richards, O.B.E.: "Considerations of Noise in the Design of Industrial Machinery and Factories".

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Chemistry Department, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. A. G. Jones: "Is It Safe in Your Laboratory?" (followed by a film).

PLASTICS INSTITUTE, LONDON SECTION ENGINEERING SUB-GROUP (at the Coachmakers Arms, 88 Marylebone Lane, London, W.1), at 6.30 p.m.—Mr. P. T. Hughes: "Thin Wall Injection Mouldings—Mould Design and Technique".

Thursday, December 16

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.E./I.E.R.E. COMPUTER GROUPS (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 2.30 p.m.—Colloquium on "Storage—Future Possibilities".

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 2.30 p.m.—Meeting on "New and Revised Test Methods".

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. H. Squair: "A Reflectometric Method of Determining the Silver Content of Natural Gold Alloys"; Dr. E. F. Stumpff and Mr. A. M. Clark: "Electron-Probe Micro-analysis of Gold-Platinoide Concentrates from South-east Borneo"; Mr. A. A. North and Mr. R. A. Wells: "Solvent Extraction of Uranium from Slurries by Means of a Rotary-Film Contactor".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Meeting on "Factors Influencing the Distribution of Amphioxus". Prof. J. E. Webb: "The Influence of Ocean Currents" and "The Nature of Deposits Colonized by Amphioxus"; Dr. W. A. M. Courtney: "Temperature as a Limiting Factor".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. J. A. Todd, F.R.S.: "A Representation of the Mathieu Group M_{21} as a Collineation Group".

INSTITUTE OF PETROLEUM, EXPLORATION AND PRODUCTION GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. L. S. Ramsay: "Geophysical Work in the North Sea".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Recording Instruments" opened by Mr. F. R. Axworthy, Mr. R. L. Hales and Mr. T. Whiteley.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. A. Gregory: "Gastrin". (Last of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation)*

CHEMICAL SOCIETY AND THE SOCIETY FOR ANALYTICAL CHEMISTRY (in the Lecture Theatre, School of Pharmacy, Brunswick Square, London, W.C.1), at 6 p.m.—Prof. W. Kemula (University of Warsaw): "The Partition of Mixtures of Homologues and Isomers by Chromato-Polarography".

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Influence of Hold Time at Elevated Temperatures on High Strain Fatigue".

Friday, December 17

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Mr. R. Bennett: "Recent Navigational Aids to Fishing".

Monday, December 20

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. D. C. Drummond: "Recent Developments in the Control of Commensal Rodents".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

EXPERIMENTAL OFFICERS (2) with a degree or H.N.D. or H.N.C. in physics or electrical engineering, and preferably experience in a research laboratory or in development laboratory) in the DEPARTMENT OF ELECTRICAL AND CONTROL ENGINEERING, to undertake the design and construction of electrical apparatus and to assist in research—Head of the Department of Electrical and Control Engineering, Battersea College of Technology, Battersea Park Road, London, S.W.11 (December 17).

LECTURER (preferably with experience in electrochemistry) in PHYSICAL CHEMISTRY (Post F/70S); and a LECTURER (preferably with experience in physiology or invertebrate ecology) in BIOLOGY (Post F/71S) in the DEPARTMENT OF CHEMISTRY AND BIOLOGY, Liverpool Regional College of Technology—The Director of Education, 13 Sir Thomas Street, Liverpool, 1 (December 20).

KEEPER (with an appropriate degree and/or the Museums Association Diploma and museum or field experience) of ARCHAEOLOGY—The Director, City of Liverpool Museums, William Brown Street, Liverpool, 3 (December 22).

ASSISTANT LECTURER (with a good honours degree in botany and/or zoology, and a special interest in cell biology and microbiology) in BIOLOGY—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (December 31).

FACULTY LECTURER IN THEORETICAL PHYSICS—The Secretary of Faculties, University Registry, Oxford (December 31).

LECTURER or ASSISTANT LECTURER in MATHEMATICS (applications will be considered in either pure mathematics or mathematical physics and it is hoped to make appointments in both fields)—The Secretary to the Council, Westfield College (University of London), Hampstead, London, N.W.3 (December 31).

LECTURER or ASSISTANT LECTURER in SOCIOLOGY in the DEPARTMENT OF SOCIAL STUDIES—The Registrar, The University, Leeds, 2 (December 31).

READER, SENIOR LECTURER and a LECTURER in the SCHOOL OF PHYSICS—The Registrar, University of Warwick, Coventry (December 31).

LECTURER or ASSISTANT LECTURER (graduate in medicine, veterinary science, dentistry, or biology) in the DEPARTMENT OF HISTOLOGY—The Registrar, University of Liverpool, Liverpool, quoting Ref. CV/345/N (January 3).

LECTURER/SENIOR LECTURER (with experience in the application of statistics to biological science) in STATISTICS/BIOMETRY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 7).

LECTURER (preferably with interests in one or more of the following: applied geography, social geography, the countries of the European

Economic Community) IN GEOGRAPHY—The Registrar, The University, Newcastle upon Tyne, 2 (January 8).

LECTURERS (2) IN CHEMISTRY (Organic, Physical or Inorganic) at the University College, Dar es Salaam (The University of East Africa)—The Inter-University Council, 33 Bedford Place, London, W.C.1 (January 8).

ASSOCIATE PROFESSOR (with high academic qualifications and practical training and experience in medical microbiology as well as experience in teaching and research) IN THE DEPARTMENT OF MEDICAL MICROBIOLOGY, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 10).

LECTURER (Grade II) IN METALLURGY WITHIN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar and Secretary, University of Bristol, Bristol (January 12).

ASSISTANT LECTURERS OF LECTURERS (3) IN THE DEPARTMENT OF PHYSICS—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (January 15).

LECTURER OR ASSISTANT LECTURER IN BOTANY at the University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (January 15).

LECTURER OR SENIOR LECTURER (suitably qualified person with special interests in organic chemistry) IN CHEMISTRY at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 15).

LECTURER (with a good honours degree in geography and if possible post-graduate research experience and specialization in surveying, cartography and mathematical geography, and preferably a knowledge of statistics) IN GEOGRAPHY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, January 15).

CHAIR OF GEOGRAPHY in the School of Earth Sciences, Macquarie University—The Registrar, Macquarie University, P.O. Box 458, North Sydney, Australia, or The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (January 17).

SENIOR LECTURER, LECTURER, ASSISTANT LECTURER and a RESEARCH ASSISTANT IN THE DEPARTMENT OF PROBABILITY AND STATISTICS (applicants may have research interests in any branch of probability and statistics)—The Registrar, The University, Sheffield (January 17).

LECTURER (specialized in theoretical and practical aspects of physical methods of analysis, particularly in relation to drugs) IN PHARMACEUTICAL CHEMISTRY IN THE DEPARTMENT OF PHARMACY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 31).

LECTURERS (2) IN THE DEPARTMENT OF BACTERIOLOGY AND IMMUNOLOGY—Prof. D. G. Evans, F.R.S., London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1 (January 31).

ASSISTANT (graduate or non-graduate) FOR A MEDICAL PROFESSIONAL UNIT for biochemical research involving automated amino acid analysis—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1, quoting Project No. 611, Ref. No. ASC/522.

ASSISTANT LECTURER IN ANALYTICAL CHEMISTRY IN THE DEPARTMENT OF PURE AND APPLIED CHEMISTRY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1.

ASSISTANT OR ASSOCIATE PROFESSORS IN THE DEPARTMENT OF PHYSICS (special consideration for one position will be given to candidates with research interests in theoretical physics)—Department of Physics, University of Victoria, Victoria, B.C., Canada.

ASSISTANT PROFESSOR (national of the United Kingdom or the Republic of Ireland, with a good honours degree and relevant experience in teaching first degree students, and preferably with a higher degree) OF PHYSICS at the Middle East Technical University, Ankara—The Appointments Office, Ministry of Overseas Development, Room 404, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 203/181/011.

EXPERIMENTAL OFFICER (with a degree in some branch of biology) IN THE DEPARTMENT OF PATHOLOGY to work as a member of a team investigating the behaviour of children's tumours in tissue culture—Dr. J. K. Steward, Tissue Culture Laboratory, Department of Pathology, University of Manchester, Manchester, 13.

EXPERIMENTAL PHYSICIST (Low Energy Nuclear Physics) (preferably with experience in the use and operation of nuclear accelerators)—Prof. L. Krause, Head, Department of Physics, University of Windsor, Windsor, Ontario, Canada.

GRADUATE (preferably with previous experience in cytogenetics) to work in the CHROMOSOME LABORATORY OF THE DEPARTMENT OF CLINICAL RESEARCH at the Royal Marsden Hospital, Fulham Road, S.W.3—The Secretary, Institute of Cancer Research, 34 Sumner Place, London, S.W.7, quoting Ref. 300/G/24.

POSTDOCTORAL BIOCHEMIST to work on the metabolism of the lens in relation to eye disease—Dr. R. van Heyningen, Nuffield Laboratory of Ophthalmology, University of Oxford, Walton Street, Oxford.

PROFESSOR (preferably candidate in the field of solid state, structure of liquids, spectroscopy or thermodynamics) IN PHYSICAL CHEMISTRY—Prof. Harry E. Gunning, Head, Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada.

RESEARCH ASSISTANT (graduate in psychology) on a three-year project concerned with the psycho-physiological investigation of chronic schizophrenia—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

SENIOR LABORATORY TECHNICIANS AND LABORATORY TECHNICIANS IN THE DEPARTMENT OF CHEMISTRY (for some of the posts technical experience in radiochemistry, spectroscopy, mass spectrometry and gas chromatography is required)—Head of the Department of Chemistry, Northern Polytechnic, Holloway, London, N.7.

SENIOR LECTURER (honours graduate) IN ZOOLOGY; and a LECTURER (honours graduate) IN ZOOLOGY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

TUTOR OR LECTURER (specialist in any branch of physics) IN PHYSICS—The Principal, Somerville College, Oxford.

NEW **grating** SP200G infrared spectrophotometer

high resolution

Unicam now offers all the advantages of a grating filter monochromator combined with the proved features of the SP200 prism spectrophotometer. The first order of the NPL grating is isolated by four interference filters, brought into play by an automatic mechanism exclusive to Unicam. The resolution is as high as 3 cm^{-1} at 3000 cm^{-1} and stray light is less than 1% throughout most of the range and never exceeds 2%. The wavenumber accuracy is better than 2 cm^{-1} at 1000 cm^{-1} and 4 cm^{-1} at 3000 cm^{-1} . To this performance are added the advantages of the flat bed recorder, the accessible sample compartment and the convenient operation of the SP200. The new SP200G is constructed and finished to the high degree of precision for which Unicam instruments are famous. Descriptive literature is available on request.

Essential *for* sampling and monitoring...

HENDREY

Mercury Vapour Concentration Meter

Type E 3472

Measures concentration of mercury vapour present in air. Essential where quantities of mercury are regularly used or where danger exists of leakage of mercury vapour from apparatus.

Two sensitivities are available at the touch of a switch, giving either full-scale meter reading at a concentration of 770 microgrammes per cubic metre of air or full-scale meter reading at a concentration of 200 microgrammes. Terminations provided at rear for operation of a recorder to give continuous readings of concentration present.

PRECISION INSTRUMENTS

NEW FEATURES—

This equipment now incorporates automatic Verdet Dispersion Correction and range change switching, water jacketed sample chamber and nitrogen purging of the optical deck.

For full details and specification,
price and delivery, write to
Dept. N.

Manufactured under licence. Patent No.918078

The electronic unit for this instrument is manufactured by Messrs. Bandix Electronics Ltd., of Nottingham

***The
POLARMATIC 62
Automatic
Spectropolarimeter***

RANGE—181 to 600 millimicrons.

ROTATION—Up to 1.4 degrees at 200 millimicrons positive or negative.

SAMPLE TUBES—5, 10 and 20 mm
standard. Water jacketed types available.

RECORDER—Flat bed plotter.

RECORDING TIME—200 to 600 millimicrons in 20 minutes.

ORGANIZATION OF THE SCIENTIFIC CIVIL SERVICE

THE sixth report of the Estimates Committee, which included some comments on the organization of the Scientific Civil Service in general, has been swiftly followed by a report from the Treasury on the organization of the Scientific Civil Service*. Much of this report confirms the views expressed in the Estimates Committee's report and, broadly, the Scientific Civil Service emerges well from both enquiries. The report from the Treasury, however, as might be expected, goes in further detail into the organization and recruitment of the Scientific Civil Service. It is accordingly of greater interest to the scientist and technologist, quite apart from the authoritative character of the Committee conducting the enquiry.

This Committee was appointed in March 1964 with Sir Mark Tennant as chairman, and included among its eight members, Sir Frederick Brundrett, Sir Charles Cawley, Sir Walter Cawood, Dr. F. M. Lea, Prof. D. G. Tucker and Sir Owen Wansbrough-Jones, with Mr. P. L. Towers as secretary. The remaining members were Mr. F. J. Doggett and Mr. D. S. Watson. The Committee was to review the organization of the Scientific Civil Service, particularly in relation to the scope for appointments made for finite periods in substitution for appointments on standard established terms, and to examine whether, in practice, the duties assigned to the three component classes were fully appropriate to their qualifications and experience. The Committee was accordingly to consider whether the 'scientific officer' class might devolve some of its responsibilities to the 'experimental officer' class, and the latter some of its responsibilities to the 'assistant officer' class and, if so, whether devolution would require changes in the structure of the classes. Any form of organization, to be effective, must be related to the purposes it is designed to serve; it should be such as to attract, and retain, sufficient people possessing the requisite qualifications, and their ability should be developed and deployed to the best possible advantage. These interacting considerations lie at the root of the matter and are accordingly covered by the Committee in its review. The report relates to the situation as it existed at the time, but the Committee believes that the substance of its comments still holds good, in spite of the substantial re-organization of civil science in the public sector.

The present structure of the Scientific Civil Service dates from the reconstruction period immediately following the Second World War, and the basis of the reorganization is set out in the White Paper on the Scientific Civil Service issued in September 1945, with the annexed report of the Barlow Committee on Scientific Staff. The new scientific officer and experimental officer classes came into existence on January 1, 1946, and a new class of assistants (scientific) was introduced a year later to relieve the experimental officer class of the more routine work. The senior class in the Scientific Civil Service is thus the scientific officer class, but a few research fellowships are also available in Government scientific establishments

at the three different levels of principal, senior and junior research fellowships. Moreover, in each of the three classes of the Scientific Civil Service, some officers serve in a temporary or unestablished capacity, constituting some 15 per cent of the scientific officer class and 12 per cent of the experimental officer class.

In both classes 80 per cent of the officers have been employed in the Civil Service for 5 years or less, while in the scientific officer class 60 per cent, and in the experimental officer class 50 per cent, have been employed for 2½ years or less. At present, including unestablished or temporary officers, some 4,100 officers are employed in the scientific officer class, 7,200 in the experimental officer class and 5,500 in the scientific assistant class. No class-to-class promotions to the three scientific classes are made under the age of 31; individuals over that age are selected at departmental discretion. Promotion within the three classes is strictly on merit.

For class-to-class promotion to the scientific officer class especially, it is clearly desirable that the standard should be both high and reasonably uniform throughout the service, and for this reason the Civil Service Commission maintains a central panel of scientists to assist departments in making selections for such promotions, as well as for promotions within the class to the principal scientific officer grade. Above this grade a substantial measure of managerial responsibility is normally involved in the work; but there are always some officers in the class whose particular interest remains centred on research and whose work clearly merits recognition. For this reason, some appointments are made each year on grounds of special merit, and the officers so promoted are enabled to continue with the work best suited to their particular bent. There are no set limits to the number of such appointments, but during 1962-64 such appointments have numbered some twenty to thirty in each year.

Commenting next on the functions and requirements of the Scientific Civil Service, the Tennant Committee points out that, while a striking feature of the Scientific Civil Service is the great variety of its work, basic research is an essential element. This wide variety of work requires a considerable diversity of talents and abilities and, while the Service needs men who can make an individual contribution to the frontiers of knowledge, there is only limited scope for those who are interested in research for its own sake and who are reluctant to accept any restriction on this field of activity. Men are needed who can visualize an end-product or a specific application and direct their research to that end. Those who are to fill the higher posts in the scientific officer class must possess, or be capable of developing, considerable managerial ability, in addition to their high scientific qualifications. The general tone and standard of Government scientific work is necessarily set by those who occupy, or may later rise to, the more senior posts, although they need the support of the experimental and other skills provided by the experimental officer class and also in turn by the scientific assistant class.

* H.M. Treasury. Report of a Committee appointed to review the Organization of the Scientific Civil Service. Pp. 28 (London: H.M.S.O., 1965.) 2s. 3d. net.

As to the merging of the scientific officer and experimental officer classes, the Tennant Committee has reservations. A unified Service might facilitate the full and proper use of the graduate talent and reduce the effect of the apparent tendency on the part of some universities to discourage graduate entry to the experimental officer class. If the classes were merged, however, there would no longer be a class with a special prestige of its own, and the Committee believes that the prestige which is attached to the scientific officer class does, in fact, appeal to the right type of recruit, while from the practical point of view, fusion of the two classes would complicate the question of probation. It is not easy to assess the relative weight of these advantages and disadvantages, but even if the Committee had believed that the balance was in favour of a unified class, it would have done no more than recommend that the idea should be further investigated. It is, however, satisfied that, in the present circumstances, the balance of advantage lies in favour of retaining the present arrangements.

Discussing next the recruitment situation, the Committee concludes that, although in 1964 the number of vacancies in established posts considerably exceeded the number of those recruited as established officers, in general the Service is attracting to the scientific officer class a fair share of the graduates it seeks to recruit, but it is rather less successful than its competitors in attracting really outstanding young scientists. This agrees with the evidence given to the Estimates Committee. Nevertheless the Committee does not believe that a system of recruitment based wholly or substantially on contract appointment would be satisfactory. If, however, ways could be found to make such employment attractive to some of those who would not otherwise enter the Service, its use might have some value as a supplementary method of recruitment, and it recommends that the possibility should be further explored.

The Committee emphasizes that the Service must be equipped to take full advantage of the increasing flow of science graduates from the universities. A proper leavening of outstanding scientific ability is essential if the standards of the Service are to be maintained. In recruitment, the nature of the work and the opportunities it offers, the idea of a permanent pensionable career, salary and career prospects all weigh differently with different people. So far as immediate salary prospects may affect the balance of individual judgment, the Civil Service may be at a disadvantage in competing with employers who have greater freedom and flexibility in making initial offers, particularly with the more talented individuals. The Committee suggests that a limited degree of flexibility in relation to starting salary might improve the ability of the Government to attract the most outstanding candidates; this possibility should be examined further. Everything possible, however, should be done to dispel present-day misconceptions about work in the Service and to build up an accurate picture of this work. This can be done, to some extent, by informal contact between members of the Scientific Civil Service and other scientists working in related fields, and every opportunity should be taken to develop such links both with universities and with industry. In particular, the Committee recommends that interchange of staff with the universities or industry, whether on a short-term loan or on permanent transfer, should be encouraged.

Quoting at length from the Barlow Report of 20 years ago, the Tennant Committee endorses the view, which the

Barlow Committee then expressed, that prospects for scientists of average ability in the Civil Service do not compare unfavourably with those offered in most universities and in industry for men of like ability. It is in regard to the man of more than usual ability that improvement was necessary then and is now. The Barlow Committee held that it was a first essential that the scales of pay and system of promotion of scientific classes should ensure that the best scientific men should have equal prospects of pay and promotion with the best men in the administrative class at least up to the top of the principal grade. This view is reiterated by the Tennant Committee, and although the Government, in the White Paper of 1945, agreed that staff complements should be so arranged as to ensure that the outstanding scientist had a reasonable expectation of reaching the principal scientific officer grade in his early thirties, its general conclusion is that the structure of the class up to and including principal scientific officer is well adapted to the needs of the work and, having regard to the terms of the White Paper quoted, provides the basis for a reasonable career. It does emphasize, however, that at a comparatively early stage in their careers some formal training in management should be available to members of the scientific officer class, although the Committee did not regard it as falling within the scope of its own review of the organization of the Scientific Civil Service to consider the question of permanent transfer to the administrative class as general purpose administrators, although recognizing the importance of the suggestion. It is, however, important that departments themselves should do their utmost to promote mobility of staff within and between their establishments. The Committee recognizes that this may involve establishments accepting some temporary inconvenience in the interests of the Service as a whole, and that the scientist himself must appreciate the advantages to be gained by widening his horizons. Nevertheless, it recommends that the effort should be made.

The Tennant Committee considered very carefully the position of the older scientists who may no longer be able to contribute materially to original research. It does not believe that the difficulty here is as extensive or as serious as is sometimes suggested, and it considers that the recommendations made as to career management and managerial training should help to minimize the problem. There may be occasional difficulties in the small establishments and in those where the main emphasis of the work is on research rather than on development. Here every effort should be made to arrange for officers to be transferred to some centre of work offering greater scope for their particular capacities.

As might be expected from a body of people of the experience and standing of the Tennant Committee, it is regarded as fundamental that highly qualified staff should not be employed on work which does not make a full call on their special qualifications, skill and experience. To do so is to waste talent and skills which neither the Service nor the country can afford, and the Committee believes that the importance of devolution of suitable tasks cannot be over-emphasized. While it is considered impracticable to define specific areas or types of work which could be devolved in this way, the Committee believes that there is still scope for further devolution but the extent can only be determined within the Department or Establishment itself. This is above all a matter for management, and is one reason for desiring to see scientific training associated with management and administration.

Commenting on the experimental officer class itself the Committee observes that many of the entrants now possess either degrees or equivalent qualifications or Higher National Certificates. This trend can be expected to become more pronounced as the flow from the universities, colleges of advanced technology and technical colleges increases, and it recommends that the arrangements for recruitment to the experimental officer class should be reconsidered. It envisages a system under which the normal age of direct entry would be the early twenties—the academic qualification being a degree or its equivalent or Higher National Certificate. Candidates without such qualifications would be recruited into the scientific assistant class in the first instance. Transfer to the experimental officer class could come when some practical skill and experience had been acquired and possibly subject also to obtaining some qualification at least equivalent to Higher National Certificate.

The Committee considers that the present structure of this class may not adequately reflect the balance and variety of its work. There is a wide gap between the accepted standard for the grade of experimental officer and that for the senior experimental officer, and the Committee thinks that there is work to be done, and being done, which is of higher quality than is normally expected of an experimental officer but nevertheless does not merit senior experimental officer grading. This situation could be met by creating a new intermediate grade, and the Committee recommends that this should be considered as part of a thorough revision of the grading and structure of the class. The future frontiers and structure of the scientific assistant class will obviously depend on the nature of any new arrangements made for the experimental officer class and could be considered when the problems associated with the latter class have been resolved.

The main recommendations of the report are in line with the comments of the Estimates Committee and also with the evidence tendered to that Committee. The report of the Tennant Committee clearly goes far deeper into the organization and use of the Scientific Civil Service than the enquiry conducted by the Estimates Committee into the Civil Service as a whole could be expected to do. While the Tennant Committee is satisfied that the scientific officer class, up to and including principal scientific officer, is well adapted to the needs of the work and provides the basis for reasonable careers, it is apparent that the recommendations of the Barlow Committee have, even after 20 years, still to be fully implemented and the way made clear to the highest posts in the Civil Service for those with the necessary administrative ability. Nor is it possible to feel entirely reassured that highly qualified staff is not being employed on work which does not make full demands on its special qualifications, skill and experience. This is never an easy task and demands much of the administrator, who may well be ill-equipped to discharge his responsibilities unless he himself has at least some modicum of scientific training or experience. There remains also the question of ensuring that the Scientific Civil Service attracts a sufficient number of really outstanding scientists. It is to be hoped that, following so swiftly after the Estimates Committee's own survey of the situation, the recommendations of this report of a Treasury Committee will not be neglected, and that steps will be taken to ensure that the necessary measures are taken as a matter of urgency.

Finally, as a tailpiece to the recommendation that the Service should take full advantage of the increasing flow of science graduates from the universities, it is worth noting that the optimism of the Robbins Report in this respect has been firmly challenged, perhaps most recently by Prof. R. V. Jones in his Joseph Payne Memorial Lecture, "The Advancement of Learning: 1605–2005 A.D." (*Nature*, 206, 129; 1965). Prof. Jones doubts whether the number of students of high ability going to universities, judged by the Ph.D. status, has appreciably increased. While university places offered in physics are not all being taken up, an increasing proportion of students do not appear to make the grade. This view is supported by the evidence of further enquiries at Aberdeen specifically in relation to physicists. If, therefore, the number of graduates of outstanding ability in physics and in other subjects is unlikely to be increased in proportion, it is the more imperative to ensure that the maximum use is made of such graduates wherever they may be employed. Prof. Jones points out further that in order to cope with the expansion planned in physics departments in the universities in the next few years some 50 per cent of all those graduating as Ph.D.s in physics would be needed to staff the universities. This is not a practical proposition; only 50 per cent would then be left for Government service, for loss by emigration, and for industry. It is in this context, moreover, that the Civil Service requirements have also to be considered. Obviously much more thought has to be given to the use made of our first-class scientific talent, including its distribution, and the most strenuous efforts made to see that such talent is not employed on duties for which those with lesser qualifications could be used.

THE FOUNDER OF ABDOMINAL SURGERY

Spencer Wells

The Life and Work of a Victorian Surgeon. By John A. Shepherd. Pp. xi+152+14 plates. (Edinburgh and London: E. and S. Livingstone, Ltd., 1965.) 30s. net.

THIS is a book with special appeal to surgeons who are interested in the history of their profession. Mr. Shepherd, a Liverpool surgeon, has carefully investigated the career and numerous writings of Spencer Wells, and is well able to appraise the results of his subject's work.

Thomas Spencer Wells was the eldest son of a builder near St. Albans. After apprenticeship to a Barnsley doctor he completed his medical education at Leeds, Dublin and St. Thomas's Hospital, London. He qualified as M.R.C.S. in 1841 and entered the Royal Naval Medical Service in the same year. Already, he had gained some distinction by a Dublin prize essay on "Bronchotomy" and was known to Sir William Burnett, the director-general of the Service.

For about seven years Wells was assistant surgeon to the Naval Hospital at Malta, where he enhanced his surgical reputation, being elected F.R.C.S. in 1844 and promoted surgeon in 1848. Between 1848 and 1850 he studied in Paris and Vienna, and travelled in Egypt and Italy in attendance on a nobleman suffering from tuberculosis. From 1851 until 1853 he was surgeon to H.M.S. *Modeste*.

A pulmonary illness caused him to be invalided home and put on half-pay. He soon recovered and was appointed surgeon to the Samaritan Free Hospital for Women and Children and lecturer in surgery to the Grosvenor Free School of Medicine. In 1855 he was appointed by the War Office as a civil surgeon to serve in the Crimean War. In 1856 he was recalled by the Admiralty, resigned

from the Navy, and resumed his duties at the Samaritan Hospital.

In the first half of the nineteenth century the mortality from surgical operations was high, and only the most daring of surgeons opened the abdominal cavity. In the majority of cases, death occurred from sepsis, and in the large metropolitan hospitals morbidity and mortality were highest from this cause. One well-recognized condition was the ovarian cyst, a slow-growing tumour.

Mr. Shepherd describes at some length the work of the early operators, the ovariologists, both British and American, their limited successes and their failures through sepsis. By 1857 the operation was in disuse and was considered an unjustifiable one by many surgeons. Nevertheless, Wells developed this operation, his first success being on a woman of thirty-eight in 1858. He faithfully recorded his cases, and soon became famous for his masterly technique. Later, when Lister had introduced antiseptics into surgery, the mortality from ovariectomy was greatly diminished.

Wells had to face much hostility and opposition. Even when the success of his operation was established, attempts were made by Clay, Lawson Tait and others to challenge his priority. Wells met all these attacks with dignity and calmness. "Only an individual possessed of the strongest will and determination could have stood up to the opposition which he had to encounter." The account of these professional jealousies makes sad reading in regard to men who must have adopted the healing art in order to benefit mankind.

In the end the claims of Wells were fully vindicated. He was elected president of the Royal College of Surgeons for 1882-83, created a baronet and accorded international fame. He died of apoplexy on January 31, 1897.

Sir Frederick Treves wrote of Spencer Wells that he "by his determination succeeded in founding abdominal surgery as we know it", and also said that his work contributed to make surgery a precise science. In this biography Mr. Shepherd gives chapter and verse for these outstanding achievements.

A. MACNALLY

PHYSICS OF THE EAR

The Physics of the Ear

(International Series of Monographs on Physics, Vol. 3.) By T. S. Littler. Pp. ix + 378. (Oxford, London and New York: Pergamon Press, 1965.) 80s.

DR. T. S. LITTLER is well known to the medical and educational profession as the director of the Wernher Research Unit on Deafness. His book, *The Physics of the Ear*, contains fifteen chapters with supplementary sections giving mathematical treatment of physical data. As the title would suggest, the subjects of anatomy, physiology and measurements of hearing are dealt with from the point of view of the physicist rather than the clinician, who would wish a greater discussion on the application to various clinical states. The approach given in the book lays an excellent theoretical and practical basis for the clinician.

The subjects of hearing and deafness have captured the attention of physiologists especially during the past twenty years when experimental approaches have been possible due to the advances in techniques for investigating nerve physiology. Dr. Littler makes a very comprehensive and critical survey of the literature to date and is to be specially commended for referring to the very early work both in Great Britain and the United States.

In the section on anatomy the most up-to-date data are described and discussed, with the possible exception that insufficient space has been given to the efferent pathways described by Rasmussen and to such work as that by Fex and Hernandez P6on. The work on the

physiology of the ear during the past 20 years has been most exciting. Dr. Littler manages to convey the wealth of knowledge we have gained in this period in a careful analytical approach to the literature, bringing out the work of Von Békésy, Davis and his collaborators but paying respect to the early pioneers.

The book gives comprehensive coverage on both the physical and physiological aspects of thresholds of hearing with reference to auditory fatigue and adaptation—a subject with which the author is himself more particularly familiar in his research. The chapter on audiometry is covered rather from the aspects of the theories of testing hearing than from a detailed clinical application to varying pathologies. This is not a criticism of a book which is not intended to be primarily a clinical text-book.

The final chapter, on "Theories of Hearing", is a most valuable conclusion to the main body of the book. It is of interest to see that Dr. Littler in planning his own book has placed this subject last. Perhaps it is a reflexion of his own thinking, which has always placed greater emphasis on experimental data as his basis of thought and action. As throughout the book, this final chapter is dealt with most thoroughly and critically.

Dr. Littler's contribution to the standardization of audiometric threshold is universally recognized. In the chapter on audiometry he reports fully on his own work in this field. The chapter dealing with the alleviation of deafness bears the stamp of his own experience, as does the section describing the development of hearing aids. The detailed description of the development of the Medresco hearing aid will be of interest to the reader. The criticism that must be offered here is that there does not appear to have been sufficient differentiation between the congenitally and acquired deaf among children and adults. The possibility that congenitally deaf children will need a different type of hearing aid from the deafened adult does not appear to have been given sufficient critical analysis.

Throughout, the book is written in a clear, readable style. Dr. Littler manages in his lucid way to bring together the many facets from the old and the new and weld together a coherent story, giving each part a perspective which will help the reader to gain an insight into the development of audiology. The book is to be highly recommended to those entering this field as well as to the experienced anatomist, physiologist and clinician. It is a book which offers a fund of information, including a valuable reference section. The publishers ought also to be congratulated on this publication. I. G. TAYLOR

MAMMALIAN POPULATIONS

Physiological Mammalogy

Edited by William V. Mayer and Richard G. Van Gelder. Vol. 1: Mammalian Populations. Pp. xii + 381. 86s. Vol. 2: Mammalian Reactions to Stressful Environments. Pp. xii + 326. 92s. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1963 and 1965.)

POPULATIONS of small mammals (that is, rodents and insectivores approximately up to the size of the brown rat, *Rattus norvegicus*) have attracted the attention of ecologists for many years and, especially since the end of the First World War, much labour has been spent on measuring their population dynamics and putting forward theories concerning the natural regulation of their numbers. Their importance lies first in their notably wide distribution and abundance as primary and, to a lesser extent, secondary consumers in most animal communities; secondly, in the wide ranges within which their numbers fluctuate and in the cyclic nature, especially in Arctic and sub-Arctic habitats, of these fluctuations. The pervasive nature of this behaviour and the frequent economic

significance of peak populations ("plagues of mice") have been broadly covered by Charles Elton in his book, *Voles, Mice and Lemmings*.

In spite of the energy which has been devoted to this problem, no clear answer has yet emerged to the question, "How are these small-mammal numbers regulated in Nature?" Nevertheless, there is no lack of theories and, indeed, of controversy about the matter. At various times the observed fluctuations have been attributed to changes in the physical environment, especially climatic cycles, to interaction between the small mammals and their natural resources, competitors and 'antagonists' (that is, predators, parasites and disease organisms) and to interaction between the small mammals themselves. The extended work of D. H. Chitty on population cycles in the short-tailed vole (*Microtus agrestis*) showed that the cycles were not necessarily synchronous and so directed attention away from the environment to endogenous factors within the populations themselves. The puzzling fact that the decline or 'crash' of a population continued down to exceedingly low densities in spite of little or no apparent damage to resources, swung attention to the possibility that physiological and/or genetic changes coincided with different phases of the population cycles. Although much work has continued on measuring the effect of food and predators, a tremendous attack has been made in the past twenty years from the physiological and social angles.

The planned series of publications entitled *Physiological Mammalogy*, of which the first two volumes are reviewed here, attempts to synthesize the vast amount of information from what might be called classical animal physiology, drawn from restricted laboratory types, with more recent work on field populations of a wide variety of species. Volume 1 contains two long articles, "The Social Use of Space", by John B. Calhoun, and "Endocrine Adaptive Mechanisms and the Physiologic Regulation of Population Growth", by T. T. Christian, both of which present evidence for the self-regulating nature of population control in (mainly) small mammals. Volume 2, with the sub-title of *Mammalian Reactions to Stressful Environments*, contains three articles, "Reproduction and Development", by S. A. Asdell, "Water Metabolism of Mammals", by Robert M. Chew, and "Hibernation", by Ch. Kayser, which can be characterized as review articles, covering an immense amount of literature, which it is valuable to have brought together here.

Calhoun has a very clear thesis to develop and argue, which is that mammalian evolution has been based on the efficiency of a social group of about twelve individuals and that most of the processes of population control, except where herding habits have been evolved, are concerned to redress aberrations from this norm. His argument concentrates on the way in which sensory contact with neighbours and exploratory behaviour conduce to home ranges organized in terms of such a social unit and in the way in which aberrations reduce viability of individuals in various physiological characteristics. Many of the data used to substantiate the theoretical steps in the argument have not been published previously, and in every way Calhoun's contribution goes far beyond the review level which predominates in Volume 2. In detail, the theoretical steps are not easy to follow for readers unused to thinking in terms of mathematical notation, but the presentation and discussion of relevant data at each step bring the argument into focus for the non-mathematical biologist. On the whole, it may be said that the data presented at each step do not invalidate the hypothesis, but whether they are susceptible of other interpretations or will be invalidated by fresh data remains to be seen.

The contribution of Christian is mainly concerned to show the mechanisms through which the various physiological disabilities subsumed under the term 'stressed' can arise in response to increasing population densities. There is more of a review quality about his article than about

that of Calhoun, and his careful and detailed account of the structure, functioning and integration of the endocrine system in mammals is an extremely valuable background to any thinking about population problems in these terms. The rest of the article examines what is known about endocrine upsets in laboratory and wild populations in relation to density, with the general theme that here is a biological system with (in the modern phraseology) a built-in homeostatic mechanism.

Both these articles deal with ways in which automatic adjustment to an 'optimum' equilibrium of numbers may be maintained, but are obscure, or reticent, about how this 'optimum' equilibrium is determined. It seems probable that this problem will remain obscure until equal or greater energy is devoted to measuring the resources of the environment.

In Volume 2 the first article, by S. A. Asdell, consists of a fairly condensed summary of the facts of mammalian reproduction and of the patterns observed in different groups. Robert M. Chew gives a very thorough account of the physiology of water metabolism in mammals (with an extensive bibliography) with special attention to their capacity to resist dehydration in arid environments. Ch. Kayser deals somewhat diffusely with hibernation.

The editors are to be congratulated on a worth-while accomplishment, involving different levels of presentation, and further volumes will be eagerly awaited.

H. N. SOUTHERN

PLATES AND SHELLS

Introduction to Plate and Shell Theory

By C. E. Turner. Pp. xii + 208. (London: Longmans, Green and Co., Ltd., 1965.) 35s.

STRUCTURES which qualify as 'plates' or 'shells' have tended for years past to receive rather limited treatment in standard texts on applied elasticity and strength of materials. This is no doubt due to the extremely varied conditions of geometry and loading that can arise, and consequently compendious and advanced specialist texts have emerged separately, of which Timoshenko and Woinowsky-Krieger's *Theory of Plates and Shells* and Flügge's *Stresses in Shells* might be quoted as classical examples. *Introduction to Plate and Shell Theory* is thus to be welcomed as a soundly written text of moderate length and moderate price which provides a thorough introduction to the field and neatly bridges the gap in existing literature.

One is glad to see a student text in which the essential and ever-repeating pattern of the actual work of theoretical stress analysis is so consciously and deliberately displayed: namely, construction of equations of equilibrium, of geometric deformation, of the assumed (normally linear) stress-strain behaviour, leading to the final and purely mathematical task of producing working equations for whatever parameters are deemed of special interest.

A short introductory chapter gives a clear account of the basic concepts of a loaded shell element. This is followed by a wide-ranging discussion of the membrane theory of shells, which, within the limits imposed by its simplifying assumptions, can so often yield remarkably useful design information in exchange for time spent on comparatively short and simple methods of calculation. Flat circular plates are then discussed for situations which involve symmetrical stretching (as with rotation or with inplane edge loading) and symmetrical bending. The conclusion to the introductory function of the book then follows in a presentation of a general theory of symmetrically loaded shells of revolution, in which cylindrical, spherical, conical and toroidal forms—together with combinations of these—are examined in some detail.

The remaining parts of the book chiefly present variations and elaborations of the foregoing themes; but

among the selected problems some useful discussion is offered of unsymmetrical bending, the influence of elastic foundations and—more briefly—instabilities, thermal stresses and melastic behaviour.

The text is supported by about sixty very clear diagrams, some short tables of mathematical functions, and a quite adequate bibliography. It should find a substantial readership among students of stress analysis and design, and has much to offer to established workers.

B. N. COLE

THE DUTCH STUDY CIRCLE FOR AGRICULTURAL HISTORY

De Studiekring voor de Geschiedenis van de Landbouw, 1939–1964

(Study Circle for Agricultural History, 1939–64.) Pp. 37. (Wageningen, Netherlands: Royal Association for Agricultural Science, 1964.)

ON the initiative of Dr. W. A. J. Oosting of Benneken an effort was made in 1937 to establish a Dutch Study Circle for Agricultural History. The plan came to fruition in 1939, but the Studiekring was set up as a part of the Nederlandsch Genootschap voor Landbouwwetenschap. Dr. Oosting was elected chairman, and J. A. van der Loeff was elected secretary with an influential committee. The intention was to study agricultural history in the broadest sense of the word; but the activities of the nascent Studiekring were brought to a standstill by the German invasion in 1940. The death of Dr. Oosting in 1942 was a great loss.

In 1944 Prof. Z. W. Sneller wrote to van der Loeff saying he had been approached by several people to form a society for the study of agricultural history, and enquiring whether the Studiekring was still operative. It was in fact in being, but in a state of war could do little, and it was decided to wait for more peaceful times. The members of the Studiekring are historians and scientists working on agricultural and kindred subjects.

Activities were resumed in April 1946. An open meeting was held and a programme of work planned. It was (1) to organize a 'history day' during the Nederlandse Landbouwweken in conjunction with the Nederlandsch Genootschap voor Landbouwwetenschap; (2) to encourage research in the field of agricultural history, and to publish the results in a series of *Agronomisch-Historische Bijdragen*; (3) to promote the publication of brief contributions to the subject in the *Landbouwkundig Tijdschrift* and to collect reprints of these in an *Agronomisch-Historisch Jaarboek*; (4) to foster the compilation of a bibliography of important articles on Dutch agricultural history from early Dutch journals; (5) to encourage the reprinting of scarce old publications of value for the purpose.

Until 1950 it was possible for the Studiekring to participate in the Agricultural Week, and the annual lectures presented were printed in the *Agronomisch-Historisch Jaarboek*. After that date this arrangement ceased. Lectures, however, continued to be read at the annual meeting of the Circle. Lectures, combined with excursions to the part of the Netherlands discussed, were also arranged each year after 1951.

Five volumes of the *Agronomisch-Historisch Jaarboek* have been published containing reprints that had been contributed to the *Landbouwkundig Tijdschrift* and other material. These appeared in 1940, 1942, 1947, 1949 and 1951. Unfortunately the *Jaarboek* had to be discontinued for lack of material. Six volumes of *Agronomisch-Historische Bijdragen* have been published, 1948, 1949, 1950, 1958, 1959, 1964. The last-mentioned bears the title *Ceres en Olio: Seven Essays on Agricultural History written to celebrate the 25th Year of the Studiekring*.

One of the Circle's desiderata was the compilation of a bibliography as a fundamental basis for the study of

farming history. A committee was set up in 1946, but after collecting some material it laid this programme aside in anticipation of the foundation of a readership in farming history at the Agricultural University. Instead a chair of agricultural, economic and social history was established in 1949. At the same time the Dutch Agricultural History Institute was formed at Groningen in connexion with the State University, one of the purposes of which was to solve the problem of publication of sources for Dutch farm history. Prof. B. H. Slicher van Bath became the first appointed to the new chair at Groningen. Thus ten years after the formation of the Studiekring the study of farming history was recognized as a subject for higher education. The bibliography that was one of the first aims of the Studiekring was finally compiled by Dr. J. M. G. van der Poel in 1953 while he was director of the Agronomisch-Historisch Instituut, and published under the title *Wegwijzer in de Landbouwwgeschiedenis*; besides its primary purpose this was intended as a guide for teachers in secondary and primary agricultural and market garden schools, who wished to teach simple farming history. A general international background is provided, but naturally the contents are mainly Netherlands sources.

Another object of the Studiekring was research into old land measures, and in 1956 a committee of three members was appointed to go into this subject. This small committee came to the conclusion that, in addition to land measures, other ancient measures and weights ought to be collected and related to those of modern times. Prof. Slicher van Bath, a member of this committee, published an *Alphabetical List of Books and Articles of Importance in Relation to Ancient Dutch Weights and Measures in A.A.G. Bijdragen* No. 11 issued by the Department of Agricultural History of the Agricultural University at Wageningen in 1964.

The work of the Studiekring has been very effective during its 25 years of life. Not only has it encouraged research and publication of results, but also it has been largely responsible for the development of farming history at all levels of education throughout the Netherlands.

G. E. FUSSELL

NOMAD PEOPLES OF THE STEPPES

The Royal Hordes

Nomad Peoples of the Steppes. By E. D. Phillips. Pp. 144 (141 illustrations). (London: Thames and Hudson, Ltd., 1965.) 30s. clothback; 15s. paperback.

THIS is a first-class publication, useful both for the specialist and for the interested layman. It is profusely illustrated, many of the illustrations being in colour. Most people have heard of the Huns, and of the danger to western civilization due to their incursions. But not everyone realizes that the Huns were only one of many hordes who roamed about the vast areas of Central Asia, stretching from Modern Russia to China, and who, starting as early as 4000 B.C., continued to flourish until only a few hundred years ago when they were finally suppressed by the growing urban civilizations of Russia and China. Nor must one think of these nomad hordes as mere crowds of savages. Nomadism was a real substitute for urban civilization, which, given the suitable environment, produced fine works of art and a not uncivilized way of life. Anyone studying the illustrations in *The Royal Hordes: Nomad Peoples of the Steppes* will have to admit that in the realm of art these nomads were by no means behind their urban opponents. The ability to produce a fine art is one of the criteria which separate man from the animals.

It is suggested that nomadism grew out of an early neolithic way of life by emphasizing the domestication of animals rather than agriculture; and with the development of the horse, a true pastoral as against a settled agricultural

mode of life became possible. It is suggested that such a development from the neolithic Tripolye culture took place as long ago as 4000–2000 B.C. in southern Russia and similarly in Caucasia, western Siberia, Turkestan, the Tarim basin and in the Far East during the same period. From 2000–1500 B.C. the movement spread, and the new way of life developed.

Naturally, the nomads absorbed useful knowledge from their neighbours. Thus the use of bronze, so important for horse harness, became general. Pottery was frequently painted and real works of art in metal, including gold, were produced. The next 500 years see the rise of the true mounted nomadism, which reached its full development about the start of our era. This mounted nomadism, of course, was especially dangerous to the urban civilizations to the West and to the Far East, and it was only when each of these latter really united that they were strong enough to destroy the nomad hordes.

There is no doubt that this is a book to possess. There is a tremendous amount of information packed into a small compass and the illustrations give a vivid picture of the splendid art of these folk.

M. C. BURKITT

INFORMATION SERVICES IN BRITAIN

The Government Explains

A Study of the Information Services. By Marjorie Ogilvy-Webb. (A Report of the Royal Institute of Public Administration.) Pp. 229. (London: Allen and Unwin, Ltd., 1965.) 28s. net.

THIS examination of the information services of the central government made by a study group of the Royal Institute of Public Administration, of which Sir Kenneth Grubb was chairman, and Mrs. Marjorie Ogilvy-Webb, writer of the report, was research officer, does not cover local government services, and the overseas information services are also excluded. It gives a thoroughly competent and readable account of the British information services and their development, which not only demonstrates the necessity of such services to-day and their essential part in the functioning of a democracy but is also to some extent an antidote to the undertones of such a book as Jacques Elliot's *The Technological Society* which visualizes the citizen being conditioned by the mass media of communication. That danger is fully recognized in this report, but sound reasons are given for believing that it is not serious in Britain.

For the most part the report is factual. After an introductory chapter describing the scope of the communications between government and governed, there are two chapters reviewing the historical development of information services from before 1914 to the present day. The next three chapters describe in succession first, the organization developed for the co-ordination of information; next, the way the departmental divisions work; and then the functioning of the Central Office of Information and of the Stationery Office. Two chapters deal with staffing the information services and with training civil servants for their relations with the public, and the final chapter contains the comments and conclusions of the examination.

It is this calm appraisal of the information services that provides the reassurance, not least because the difficulties are frankly faced. No charge of political bias has ever been properly sustained against the information services nor are individual members of the information services known to have engaged in political controversy. Nevertheless, the whole question of impartiality is very difficult, and there is much in this final chapter for the scientific or technical adviser to ponder. The creation of an informed public opinion where scientific and technical issues are involved is not always simple and, although

such issues are not discussed directly in this book, its implications for such issues are easily discovered, though the only factual slip I have noted is an inaccurate reference to the Advisory Council on Scientific Policy. Bibliographical references appear to be fairly complete although the manner of citation is not always the most convenient and there are places where more biographical references might have been included: apart from Lord Reith's *Into the Wind*, these are largely lacking. One thing at least this report should do: it should prevent any raising of the old controversies and ensure acceptance of the information services by the major political parties, while stimulating the continuous thinking about their functioning and the constant vigilance that are the safeguards against abuse. Not least, it should contribute to establishing the information services on a level of esteem and status that will help to attract to such a career men and women of the character and ability demanded if the service is to be of the highest standard.

R. BRIGHTMAN

IRISH BIBLIOGRAPHY

A Guide to Irish Bibliographical Material

By Alan R. Eager. Pp. xiii+392. (London: The Library Association, 1964.) 96s.

THE National Library of Ireland is at present preparing what will be the first attempt at an Irish national bibliography. Eleven volumes, dealing with manuscript sources, should appear later this year. As an interim measure, Mr. Eager has compiled a bibliography of bibliographies listing more than 3,800 items arranged broadly according to Dewey.

Much of the material consists of catalogues and printed bibliographies. Many of these, however, are not specifically, or even predominantly, Irish in coverage. General works such as the *British Union Catalogue of Periodicals* and *World List of Scientific Periodicals* are included so that Eager duplicates much of Walford and Winchell, without their annotations.

The comparative paucity of Irish bibliographies has tempted Mr. Eager to stray beyond the limits one would expect. In his anxiety to record at least one reference for every subject he has "included works which are not bibliographies *per se* but are standard or representative, also articles which appeared in periodicals and newspapers that are of value but are not generally catalogued separately and are thus overlooked". The dangers of such a policy are obvious, and Mr. Eager has not avoided them. Under "Domestic Science", for example, the only sub-heading is "Hotels, Restaurants, etc.", and of the five items listed, four are accommodation guides; the fifth is the history of a Dublin hotel. In such circumstances would it not have been better to ignore the subject completely?

Articles from periodicals, the other type of material, are very often from journals such as the *Proceedings of the Royal Irish Academy*, to which reliable indexes already exist and which any competent research worker would consult as a matter of course.

Criticism of this book revolves around Mr. Eager's too-good intentions. Sins of omission are rare, and if the compiler had set out to produce a vade-mecum to Irish studies the book would have been a praiseworthy beginning. Even so, one might have wished for a standard approach where the expansion of initials into forenames was concerned. An unfortunately haphazard presentation has been adopted.

Nevertheless, Mr. Eager's book has already become a standard reference tool, and we should be grateful for the accuracy and care in its compilation which are obvious throughout, especially in recording unpublished manuscripts and work in progress.

H. J. HEANEY

The Fossil Evidence for Human Evolution

An Introduction to the Study of Palaeoanthropology. By Sir Wilfrid E. Le Gros Clark. Second edition, revised and enlarged. (The Scientist's Library.) Pp. xii + 201. (Chicago and London: University of Chicago Press, 1964.) 6 dollars; 45s.

THIS revised edition of *The Fossil Evidence for Human Evolution* comes at an appropriate time and 10 years after the original publication. In 1954, Piltdown had been relegated to the history of fakes and forgeries and the human evolutionary picture was all the better for the removal.

The 10 years that have passed have seen fewer crises and the emergence of a much more satisfactory realization of man's ancestry. Much of this has depended on the labours of a few men: the prescience and persistence of Kenneth Oakley, who has added a new system of time to human studies; the labours of John T. Robinson on the splendid collections of Australopithecines that he has had to leave in South Africa on his translation to Wisconsin; and always the genius of L. S. B. Leakey in charming fossils from the ground.

All this has clarified the general view, if some aspects of it are a little clouded. Most systematists will heartily agree with Sir Wilfrid that there are too many names along the route of man's emergence. While it is true that in these pages *Pithecanthropus* and *Sinanthropus* are now less frequently mentioned and *Homo erectus* stands more neatly in their place, yet the Australopithecines bristle with genera from A to Z. There is much to be said for the author's plea that, until they become systematically established, specimens might bear such names as "the Steinheim skull", the "Swanscombe skull", etc., rather than a too hasty attribution to a new genus and species. On the other hand, human palaeontology is of general interest and a new genus may more easily and more widely be recorded.

The increase in the size of the new text is largely due to valuable descriptions of the methods of dating remains. Fluorine, carbon-14, potassium-argon and uranium-lead are dealt with. It is interesting to note that dates in the Pleistocene are being lengthened and put further back. *Homo sapiens* had a history of 50 thousand years in the 1954 edition. Now it is 200 thousand.

This well-produced volume is a necessity for all who work in human palaeontology. Others will also appreciate the quiet wisdom and the well-turned phrases of its distinguished author.

W. E. SWINTON

Mathematical Analysis

Functions, Limits, Series and Continued Fractions (International Series of Monographs in Pure and Applied Mathematics, Vol. 69). Edited by L. A. Lyusternik and A. R. Yanpol'skii. Translated by D. E. Brown. Pp. xiv + 404. (Oxford, London and New York: Pergamon Press, 1965.) 70s.

THE content of *Mathematical Analysis* is somewhat wider than the sub-title suggests. There is a chapter on n -dimensional spaces, functions defined there, linear operators, convex bodies; the work on series includes a considerable amount of material on orthogonal series and systems of orthogonal polynomials; there is a short section on special functions, such as the Bernoulli and Euler numbers, the elliptic functions, the gamma function, Bessel functions. The material is logically arranged and clearly set out, but no theorems are proved. It is thus difficult to know how the book is to be used, and it is a pity that the editors do not tell us how this and succeeding volumes fit into the Russian techniques of instruction. The arrangement is scarcely suitable for a book of reference, but the absence of proofs would prevent it being an adequate text for private study. If a teacher were to select the more difficult key theorems and go through them in detail with his pupils, they might then, granted time

and patience, derive very substantial benefit by working carefully through the rest of the book, proving the subsidiary theorems and verifying the numerous formulae. There is, for example, an immense amount of information stored away in the chapter on orthogonal polynomials; and to verify the couple of dozen integral forms, not all entirely trivial, for Catalan's constant would make an admirable revision exercise in the technique of definite integrals. Perhaps if later volumes are translated, a prefatory word on how best to use them could be added.

T. A. A. BROADBENT

Power Travelling-wave Tubes

(Applied Physics Guides.) By J. F. Gittins. Pp. xii + 276. (London: The English Universities Press, Ltd., 1964.) 50s.

TRAVELLING-WAVE tubes have played such a unique part in the development of microwave communication links that they well merit close examination. Not only in their conception are they the result of an impressive flight of imagination, but also in their construction they incorporate some of the most recent technological developments.

Power Travelling-wave Tubes gives a very successful presentation of most problems involved in the design of travelling-wave tubes. In view of the emphasis put these days on the importance of advanced engineering education, it is encouraging to find a book which is prepared to tackle not only the fundamental but also the technological side of a problem.

The author discusses both forward and backward wave amplification processes, including crossed-field interaction. The operating of travelling-wave tubes is explained using Pierce's approach, but a commendable use is made of vector diagrams to illustrate many points. Separate chapters discuss slow-wave structures, electron guns and collectors and transitions, severs and radiofrequency windows. The two final chapters deal specifically with vacuum and measurement techniques.

The book can be recommended as an up-to-date description of an important field of vacuum tube technology and it is a welcome addition to technical literature.

P. A. LINDSAY

Structure Antigénique de Tumeurs Expérimentales

Par C. Deckers. Pp. 180. (Bruxelles: Editions Arscia S.A.; Paris: Librairie Maloine, S.A., 1964.) n.p.

THIS is a monograph covering several years' work by Dr. Deckers, dealing with the analysis of antigens in rat tumours by the methods of Ouchterlony double diffusion and immunoelectrophoresis. Several methods for increasing the sensitivity of the gel diffusion technique were described. The most sensitive of these used a combination of immunoelectrophoresis and double diffusion in gel. Hyperimmune rabbit sera were used in all the investigations involving rat tissues. Five organ-specific liver antigens were demonstrated in normal rat liver. During the course of chemical carcinogenesis of the liver, the concentration of organ specific antigens progressively diminished. In transplantable hepatomata, there was only one such antigen remaining. However, a new antigen was detected in a transplantable (HA) hepatoma. This new antigen could not be detected in other tumours. Attempts to provoke circulating antibodies to the HA antigen in rats were unsuccessful, as far as the means of detection would allow. Inoculation of rats with HA tumour extracts either slightly decreased or increased the rate of growth of tumours transplanted later.

The efforts of some of the other workers in this field were mentioned. The author deserves credit for persisting in a problem which poses many experimental difficulties, and it will be interesting to follow the progress of the work.

ROBERT R. DOURMASHKIN

THE ROYAL SOCIETY

ANNIVERSARY ADDRESS*

By Lord FLOREY, O.M., P.R.S.

AWARD OF MEDALS, 1965

Copley Medal : Prof. A. L. Hodgkin, F.R.S.

THERE are few areas of modern knowledge the development of which can be identified with the leadership of one person. Yet, in the field of neurophysiology, the important and indeed decisive advances which have been made during the past 30 years are almost wholly due to the original work of A. L. Hodgkin and to the influence which the theoretical concepts and experimental techniques developed by him have had on research workers all over the world.

In his earliest paper, published in 1936, Hodgkin showed that the cable-like structure of a nerve fibre provides an essential link in the conduction of the nerve impulse, and that the electric current generated during excitation of a small part of a nerve fibre can stimulate a region of a few millimetres length ahead and so propagate with a large safety margin. This was Hodgkin's first experimental exercise, in which he still used established techniques. To advance the study of the nerve impulse further, he decided to adopt a more direct approach, by working on isolated cells and measuring their membrane properties with the help of micro-electrodes introduced into the cell interior. This led to a new kind of experimental analysis, far in advance of what had been attempted before. Hodgkin's decision to embark on this project and his refusal to be deterred by what must have seemed appalling technical difficulties have led, during the past 20 years, to a gradual revolution of the whole neurophysiological field.

Hodgkin's experiments resulted in the discovery of the ionic mechanism of the nerve impulse. He showed that the action potential wave arises from a rapid entry into the cells of a small quantity of sodium ions followed by an equivalent loss of potassium ions from the cell interior. The initial influx of sodium is a regenerative process which propagates along the whole length of the fibre. The impulse derives its immediate energy from the ionic concentration differences between the cell and the surrounding fluid.

In a series of investigations extending over 20 years, Hodgkin and his pupils have worked out the quantities of the ion movements across the nerve membrane and the rates of the underlying permeability changes, and more recently have been bringing to light the chemical reactions involved in the restoration and maintenance of the ionic store of the cell.

Hodgkin has had the enthusiastic collaboration of many distinguished pupils and has built up a school of physiologists of high international reputation. Moreover, his techniques of intracellular recording and the directness of his single cell analysis have served as a model which has raised the standards of experimentation in a wide area of physiological research. The new concepts explaining bioelectric phenomena in terms of specific ionic conductance changes have not only had a far-reaching influence on the study of peripheral nerve and muscle, but have also led to important advances in the investigation of the synaptic mechanisms in the central nervous system.

A Royal Medal : Dr. R. A. Lyttleton, F.R.S.

Dr. Lyttleton is distinguished for his theoretical studies in many fields of astronomy and geophysics. He has shown outstanding ability in the application of dynamics to astronomical problems, and his book, *Rotating Liquid Masses*, is a unique description of work on obscure classical problems that few scientists have hitherto been able to understand. In his work he has finally clarified problems which puzzled many distinguished theorists such as Jacobi and Jeans. In particular, he elucidated and clarified the important result that the disruption of a fluid mass by rotation would not lead to a pair of bound bodies, as Jeans believed, but to two independent bodies. His work on this subject has had major repercussions on several contemporary problems in astronomy, especially on the formation and stability of galaxies, on the origin of the Solar System and the capture of satellites by planets. In earlier work (in collaboration with Hoyle), Lyttleton evolved from Cowling's pioneer effort the first satisfactory model of a main sequence star and gave the first correct specification of the boundary conditions in stellar interiors. He has made many contributions to the problems of the interstellar medium, particularly in the examination of the interaction between stars and interstellar matter and the problem of accretion. His work on comets, on which he has evolved almost the only existing truly physical theory, is widely known and he has made many contributions to the problems of the constitution of the Earth and the planets. Lyttleton is also well known for his studies in cosmology; indeed there are few subjects in contemporary astronomy which have not been stimulated and enriched by his work.

A Royal Medal : Dr. J. C. Kendrew, F.R.S.

Dr. Kendrew has for many years conducted an intensive investigation of the molecular structure of sperm-whale myoglobin and has the distinction of having revealed for the first time the full three-dimensional arrangement of the atoms in a protein molecule. This successful culmination of more than 20 years' work is a landmark in the history of biology. It is now possible to interpret much of the biological function of this molecule in chemical terms and to begin to see how the many activities in living organisms which are controlled by proteins can be explained at the molecular level.

Kendrew and the group working in the Medical Research Council Unit at Cambridge have given a powerful impulse to the establishment of molecular biology as a new branch of science. This group has brought together in the elucidation of macromolecular structure a large number of different techniques and, in particular, have shown how X-ray diffraction can extend the range of structural analysis down to the atomic level, even for the most complex molecules, by the use of electronic computers. Kendrew's success is an indication of his insight in the choice of a particular molecule on which to concentrate his efforts, but he has constantly directed attention to the general principles of macromolecular architecture which are exemplified in the structures he describes. • It is largely

* Delivered at the Royal Society on November 30.

due to him that the ultimate solution of the problem of form and function in biology is no longer a matter for the philosophers but is a goal which can be reached by patient experimentation.

A Royal Medal : Dr. H. C. Husband, C.B.E.

Dr. Husband is distinguished for his work in many aspects of engineering, particularly for his design studies of large structures, such as those exemplified in the radio telescopes at Jodrell Bank and Goonhilly Downs. He has achieved great success in his co-operative work with the scientists in the evolution and construction of these instruments which have been so important to British science and technology. Husband was presented with the concept of the large radio telescope in 1949 and agreed to undertake the design and construction of the fully steerable 250-ft. aperture paraboloid, at a time when several other engineers had rejected the problem as practically insoluble. The scientific specifications presented him with a complex of interesting structural, mechanical and electrical problems which had never before been faced. His work on these problems and on those later arising in the smaller precision telescopes is typical of his skill in co-ordinating the efforts of engineers and scientists in the solution of unusual structural difficulties, which has led to the successful completion of many public works in Britain and abroad. He brings to this work some of the width of interest shown by the great engineers of the nineteenth century, together with the persistence so necessary for success in such fields.

Davy Medal : Prof. H. W. Thompson, F.R.S.

Prof. Thompson's major contribution to chemistry has been the application of spectroscopy, especially infra-red and Raman, to a wide range of chemical problems, although he has also been responsible for important pioneering work in gas kinetics and in photochemistry.

The early spectroscopic work involved the determination and assignment of the vibrational frequencies of small molecules, the calculation from these of the force constants of chemical bonds and the correlation of both with structural features of molecules. He can justly be described as one of the pioneers in the application of infra-red absorption spectroscopy to the problems of structure and analysis of larger molecules, for which he had to devise experimental methods which at the time were novel. These techniques involved improvement of methods for measuring the spectra and also the devising of methods of handling samples in all phases and over wide temperature ranges. During this period Thompson made substantial contributions to the establishment of characteristic group frequencies covering many structural classes of chemical and biological interest. He was the first to study polymers in this way and to use polarized infra-red radiation for the study of oriented polymers and crystals. A novel and fascinating extension of this work was his combination of the reflecting microscope with an infra-red spectrometer to investigate minute crystals and fibres.

He has also made extensive measurements and theoretical analysis of the rotational fine structure of vibration bands of small molecules in the vapour phase, in order to obtain the molecular constants and geometry, and to extend the theory of molecular energy-levels. Some 20 years ago, he was a pioneer in the use of the newer photoconductive cells so as to obtain much higher resolution in the infra-red. Some of the resulting data on small molecules are now accepted for secondary wave-length standards, by the international commission concerned. The command of these techniques permitted him to execute a lengthy programme on the intensities of vibrational absorption bands of key groups, and their interpretation in terms of bond polar properties and molecular-

structural features. He was one of the first to construct a photoelectrically recording Raman spectrometer, and has measured Raman spectra in studies of molecular structure, for the determination of molecular vibration frequencies, and in studies of intermolecular interactions.

More recently, he has used spectroscopic methods to investigate intermolecular forces and the formation of complexes, using solvent effects on vibrational spectra, pressure-broadening studies on rotational lines, the measurement of hydrogen bonding equilibria, and other systems.

Hughes Medal : Prof. D. H. Wilkinson, F.R.S.

Prof. Wilkinson is outstanding in the group of experimental nuclear physicists who started research in Britain in the closing years of the Second World War. At that time he was enrolled as a member of the British atomic energy team working in Cambridge, and he very quickly established himself as an investigator of originality and drive. Wilkinson has made a very detailed study of the validity of charge independence in nuclear physics, and in a long series of papers (written in collaboration with his students) he has analysed isobaric spin selection rules applicable in many nuclear transitions. Recently he has developed a mass formula applicable to the components of iso-spin multiplets.

In recent years his interests in nuclear structure problems has led to a series of important experimental studies of short-lived excited states of light nuclei using pulsed beam techniques. Wilkinson has also made contributions in the field of high-energy physics. Perhaps more than any other physicist he has been quick to see the relation between the concepts of high-energy physics and those of nuclear physics. For example, in a series of papers he has analysed the validity of parity conservation in strong nuclear interactions.

He has been particularly fascinated by the possibility of using elementary particles as probes for the study of nuclear structure. He pointed out that certain observations on the capture of *K*-mesons by complex nuclei received their natural interpretation on the assumption that nucleons in the surface of nuclei tend to form closely knit clusters, and he has proposed methods of studying the detailed structure of the nuclear surface by measurement of the intensity of *K*-mesic X-rays. These methods appear likely to be of considerable importance when stronger beams of *K*-mesons become available.

Wilkinson has also made important contributions to the discussion and evolution of national policy in relation to nuclear energy and high-energy physics, and recently acted as chairman of a representative committee to report particularly on future British policy with respect to high-energy accelerators.

PRESIDENTIAL ADDRESS

No doubt more than one view can be taken of the purpose of the President's address. Some might consider that a specific scientific field should be singled out for pointed comment and a large, if figurative, sign erected to indicate clearly the road ahead. Others might expect some philosophical discussion of difficult contemporary problems while still others, possessed of the necessary cynicism characteristic of modern sophisticated society, will know that to-day the address is largely to fill in some 30 minutes or so before the very important manoeuvre of inducting my successor.

I propose to devote this time to considering some of the affairs of the Society, but I wish to avoid giving any impression that even now I know everything about how the Society works, still less that I can instruct my successor and his colleagues in how to deal with the many problems which confront it.

While preparing for to-day I re-read Sir Cyril Hinshelwood's masterly Tercentenary address (*Nature*, 187, 274; 1960). He gave a summary of the past activities of the Fellows of the Society, he touched on the functions performed by an Academy, and he mentioned the uncertain and unknown future of science and its relationship to creative thought and even to the evolution of society. He said, after discussing specialized organs of Government and the universities, "an Academy, therefore, is a natural body to provide for several vital things; non-commercial periodicals for the publication of discoveries, a measure of financial support for ideas still too embryonic to be of immediately obvious practical application, the mutual stimulus of association and discussion and the immaterial award of honour for intellectual achievement".

Perhaps I can begin by discussing 'financial support for embryonic ideas'. The Society serves a useful purpose by dispensing sums of money which are in fact almost negligible compared with those now handled by a number of Government agencies. In spite of the small amount of money available, the grants we are able to make are greatly valued by the recipients, and Fellows are glad to devote their time to the careful scrutiny of applications. From 1947 until 1955 Council was able to grant about 66 per cent of the amount applied for. In the year ending March 1965 the figure was 36 per cent. Expressed another way, to have granted last year as big a proportion of requests as 10 years ago would have needed £170,000 instead of the £100,000 which we had at our disposal. It should be added that the drop in the number of people we were able to support was not due to any falling off in the excellence of the proposals made to us. Perhaps our recent experience merely underlines what is becoming only too painfully obvious, and that is that the resources the country is prepared to devote to scientific activities are insufficient to meet the demonstrable current needs, and present indications are that the amount of money available is not likely to increase substantially in the foreseeable future.

Perhaps the deployment of Government resources is the modern equivalent of events in the early days of the Society when Fellows contributed—or sometimes did not contribute—a shilling a week towards demonstrating experiments at meetings. There never was enough money.

We are now all familiar with the large financial backing that has to be put at the disposal of those who wish to pursue what is called 'big science'. Even the general public seems prepared to back these expenditures, or at least no loud outcry against them has arisen.

The idea that very expensive experimental equipment must be shared at some central institute or laboratory is fully accepted on both a national and an international basis, and in the most advanced form of expensive physics we are approaching the time when co-operation on a world scale will be achieved for the construction and working of gigantic apparatus. But perhaps we should be taking a sharper look at whether more could not be accomplished by greater national and international integration in smaller, though still expensive, scientific endeavours. So far as scientific discoveries are concerned it should not matter whether they are made in Oshkosh or Vladivostok. The same, of course, cannot be said of technological innovations or developments, simply because the world is divided into fiercely competitive units each one trying to outdo the others for economic reasons. Nevertheless, within the framework of contemporary political systems, much more could, I believe, be done to forward discovery by making use of selected environments throughout the world in which concerted efforts could be deployed. By this I mean that instead of spreading our national resources too thinly between too many institutions we should concentrate on 'centres of excellence', and from firm national bases international 'centres of excellence' could be

formed. We might then hear less of 'brain drains', and if some of our best people did go to work in other countries, their going would be balanced at least partially by a reverse flow.

This might not be entirely unpractical in dealing with, for example, institutions in the United States with which scientists of Britain have such good relations and with which it is easy to communicate. It should not be insuperable in dealing with Western Europe where, although something has been attempted, we are still making far too few conscious efforts to organize co-operative work. At the present time we are even deficient in the amount of scientific discussion we have with our near neighbours. Is it that we are unwilling to become good Europeans? If so we should consider whether this is wise.

When we look at the Iron Curtain countries we have to be content with relatively little. Agreements reached with the U.S.S.R. and other communist countries spell out in detail exchange arrangements with which we are all pleased, but real international working has scarcely been touched.

I am sure that most, if not all, hard-headed administrators of science would look on the accomplishment of what I have dimly outlined as far too Utopian to contemplate at all. And yet the Royal Society prides itself on its extensive international connexions, its contributions to the International Council of Scientific Unions and its fostering of the exchange of scientific ideas. I wonder if the time might not come in the next 15 or 20 years when the Society might find it to be for the benefit of scientific endeavour to lead in the direction of greater international co-operation, not only at the conference-level but at that of the bench. Perhaps we could play a real part here.

But of course Britain needs something not only in which scientists and technologists can take a pride but in which the general populace, who now have to provide the resources, can also be interested and about which they can be informed. What an inestimable boost to national morale the great programmes for the exploration of space must give in the United States and the U.S.S.R. Is it now quite beyond our capacity as a nation to become really mentally and physically stretched to the limit in cultivating some field of activity? Can we canalize any great scientific adventure of which the whole country could be proud? Could we make a really great mark in exploring the under-water world, for example, rather than making what at present seem to be somewhat pathetically inadequate, though scientifically and technically competent, efforts to enter the same fields as the great rocket powers? Could not a country that mounted the great *Challenger* expedition foster oceanography and the exploration of the possibilities of the sea, its water, and what is beneath it, so that it would be our national pride and joy? But perhaps you are thinking that I am asking too many silly questions.

I will instead make a statement. It is that there is now overwhelming evidence that rapid population growth is bringing with it dire consequences, not only in the great Asiatic countries but probably even here. Evidence is slowly accumulating that the question is not simply whether food can be supplied for an ever-increasing population, but whether overcrowding *per se* does not lead to obscure and so far ill-defined difficulties of mental and social adjustment to a crowded and rapidly changing environment. Observations on animals are certainly pointing to some such possibility. Perhaps we should be paying more attention to the generally unpleasing form that life is assuming in great cities.

It may be that to relate population to environment optimally is the greatest technological task of the end of this century. Its solution will not depend on biological science or medicine alone. It will involve every discipline from economics to psychology. Would the Royal Society serve the nation in a wider sense and science in a narrower sense by taking a greater interest in some of the questions

I have mentioned? To become significantly involved in such matters as these will require more resources than the Society can at present command, and indeed perhaps more than the country conceives that it can afford, though this would depend on the great modern game of 'allotting priorities'.

At the moment it is considered to be desirable to give free medicine to all. The application of free calamine lotion to the irritated skins of the populace may be more important than administering to the needs of irritated scientists; but this sort of judgement is in the realm of politics and, as you know, we do not mix ourselves in these matters here. Still, one cannot help wondering, only of course when we are outside Burlington House, whether the priorities now being chosen are right for the ultimate well-being of Britain.

In connexion with resources for research I need scarcely mention that we have been witnessing during the past 18 months or so a reorganization of the ways in which Government assistance is given for scientific and technological research, development and education. Fellows of the Society might well be advised to take an increasing interest in the way in which these organizational matters are handled, for we may be approaching a state which was popularly advocated some 20 years ago, when it was said that scientists should be on tap and not on top. Perhaps the Royal Society as a collection of active scientists might have something to say on these tendencies.

Coming now to the "immaterial award of honour for intellectual achievement", there is one point that particularly deserves comment this year. This is the first time that the new Royal Medal for merit in the technological field has been awarded. The gracious act of Her Majesty in instituting this new honour is very greatly valued by the Society, for we are particularly delighted to have been enabled by this Medal further to proclaim that the Society wishes to continue to foster the applied sciences.

Perhaps I could now turn to the theme of "the mutual stimulus of association and discussion". During about nine months of the year the Society meets frequently on Thursdays, as is its ancient custom. I suppose that anyone who has sat in this chair, and has been in the privileged position of not understanding the paper being given and so of being able to survey the audience, will have wondered whether these exercises still serve a useful purpose. These doubts seem to be shared by Fellows, for it must be confessed that at times I look around to see how many of them are present and I have long learnt on such occasions not to ask if there is a quorum for conducting the business of the Society. The great growth of specialized societies may have diminished the importance of the delivery of papers at our meetings. Perhaps in view of the multiplicity of calls on the time of Fellows and the numerous activities of the specialized societies we now meet formally too often. Be that as it may, it has long been the policy of the Society to have symposia and lectures, and we are greatly indebted to Prof. W. T. J. Morgan and the Hooke Committee for setting in motion in the recent past the organization of many admirable meetings of this kind. They have grown to such an extent that they have almost succeeded in displacing the delivery of original papers. Some of these meetings have been very popular not only with Fellows but also with many other scientists working in the broad fields covered by the meetings and, thanks to the Tercentenary Appeal and other sources, we have been able to welcome among our speakers prominent scientists from abroad. The popularity of such gatherings has brought difficulties. Thus, on one occasion, we had to migrate to the lecture theatre of the Shell Building on the South Bank. On another occasion we went to the Zoological Society in Regent's Park, and on the occasion of a joint meeting with the Genetical Society we went to University College, London. To all our hosts on these occasions we are much indebted. But one consequence of this peripatetic existence has been that we have had to procure a coffin-

like box for the transport of the mace, and I am sure that our original Fellows, and even Charles II himself, might have been somewhat astonished at the adventures of their royal emblem.

The increased volume of publication associated with these activities has thrown a crushing burden on the editorial staff of the Society, which brings me to another of Sir Cyril Hinshelwood's headings, the support of 'publication'. A number of the symposia and papers at discussion meetings are published as separate issues of the *Philosophical Transactions* and the *Proceedings*, and this puts great demands on Mr. J. C. Graddon and his staff. I should like to take this opportunity to express to them on behalf of the Fellows our gratitude for all their splendid efforts to keep our publications up to their excellent standard. But of course it has not escaped the attention of the Officers that a number of Fellows are dissatisfied with the time taken for publication in our *Proceedings*, especially *Proceedings B*. I would ask Fellows to be patient, and to be sympathetic with those who are trying to produce these journals under considerable physical difficulties. I should like to say, however, that so far as *Proceedings B* are concerned, we lack that vigorous support from Fellows which we could legitimately expect. May I take this opportunity to appeal to those on the biological side to support the journal more than they do at present, either by contributing papers themselves or by seeing that those whom they can influence submit work for publication.

I have now the very great pleasure of announcing the biggest single benefaction that has been received in the history of the Society. The trustees of the estate of the late Mr. M. S. Napier have arranged to transfer to us the sum of £275,000 to be used in the broad field of cancer research. For the first 5 years the income will be used to assist a project at the Institute of Cancer Research at the Royal Marsden Hospital, and thereafter the Society will be free to apply the income in the ways it deems best under the terms of the Trust. We are greatly indebted to the trustees for so munificently increasing our resources for research in biological fields.

There is one matter which affects the future welfare of the Society and of all its Fellows. I refer to accommodation. Before, however, I mention what is happening I should like to make another quotation from Sir Cyril Hinshelwood's address. He said: "There has seldom, if ever, in the world's history been a time when existence was not in some degree precarious, yet the right response to danger lies in action. Faith in the future has indeed a very great survival value. The better equipped are certainly more likely to survive than the worse equipped and not only to save themselves but to save others".

These noble sentiments, if such I may call them, were of great assistance to me and I think to the other Officers and members of Council as we clasped our heads while making some crucial decisions in the so-called 'dog days' of last summer.

You will remember that we had been confidently assured that we should be able to transform the inside of our proposed premises in Carlton House Terrace to meet our purposes for about £500,000. In the summer, after a very careful look at the detailed plans and estimates, it became clear that we could not get into Carlton House Terrace without having raised £850,000. Fortified, at least in my case, by the words I have quoted, the lease for Nos. 6-9 Carlton House Terrace has now been signed and work has begun on transforming the interior. Unless unforeseen circumstances arise, the building should be ready for occupation about July 1967.

In order to proceed with our plans, which those intimately concerned with the Society regard as essential to our future welfare, we shall have to run into a very serious debt unless we receive further generous donations. Steps are being taken to extract us from this extremely difficult position. We have sufficient faith in our friends in the

community in general to feel confident that the oldest scientific Society in the world, and one which in the past has inspired so much scientific work not only in Britain but in other countries, will not be allowed to fail or even falter from the lack of the material assistance which we now so urgently require. Preparations are well advanced for a general appeal not only for the new accommodation and facilities but also for funds to make the best use of them.

I must confess that it is for me a cause of great regret that I shall leave office without having been able to see completed the task of raising the money to equip the Society with the accommodation which it so desperately needs, if it is to continue to play its part and to expand its activities as it should in the modern, rapidly changing scientific world.

The somewhat gloomy thought that possibly through some misjudgement of mine something will now go seriously wrong with the finances of the Society gives emphasis to the fact that I have never ceased to be astonished that the Society should have done me the supreme honour of electing me to this office. I came very ill-prepared for the tasks it involves, and I should not have lasted until to-day but for the very sympathetic understanding and help of all the officers, the support of Council, and the forbearance of the Fellows.

To-day there is what might be called a considerable turn-over in officers. I am most indebted to the retiring 'A' Secretary, Sir William Hodge, and the Foreign Secre-

tary, Sir Patrick Linstead. Both have had a great deal to do with the handling of the ever-increasing activities of the Society. During his period of 8 years as Physical Secretary Sir William Hodge has played a significant part in the Society's contribution to the nation's scientific research programme in space, and during Sir Patrick Linstead's term of office there has been a very substantial increase in the Society's international relations not only within the International Council of Scientific Unions but also in inter-academy relations and in exchange arrangements. I am sure you would like me to express to them the gratitude of the Society for what they have done for it during their term of office. We welcome the new officers and wish them well in what they will find to be an onerous job.

My thanks and those of the Society are, as always, due to Dr. D. C. Martin, Dr. R. W. J. Keay and their colleagues for all the loyal and informed work they have done for us during the past year, often in ways which are quite unperceived by Fellows in general.

It now remains only for me to wish my successor in office as happy a time as I have had. I am sure the Society will face the future with greater confidence than it has had before, for I believe that, by suitable adaptations to the changing environment in which scientific and technological work will be carried out, the Society will have an even more honourable future than it has had a glorious past.

CONSERVATION AND MAN'S ENVIRONMENT*

By DR. IAN McTAGGART COWAN

Dean of the Faculty of Graduate Studies, University of British Columbia

THROUGH the millennia of his birth, man was a poorly equipped, struggling omnivore inhabiting environments which offered special favour. Populations were small, and the product of a limited area was the sole support of its humans.

As man the inventor, however, he added to his inadequate physical attributes a long series of devices which extended his ability as a food gatherer and expanded his environmental tolerance.

With increasing competence, the itinerant hunter-food gatherer in his family group became the neolithic agriculturist. This was certainly subsistence agriculture, but it permitted the first permanent settlements and therewith the first truly man-made environments. The discovery of the river basins with their rich soils led to the production of food surpluses and with these the specialists, the villages and later the cities.

Through these years when every man was an intimate daily participant in the struggle to wrest survival from an unpredictable environment, a rich store of folk images grew from the day-to-day experiences. These guided his biological routines and provided acceptable explanations for the commonplace physical and biological phenomena. He was an observant and rational creature, and here and there across the world developed some effective practices to prolong the food-producing ability of his habitat. These folk techniques, however, were family or tribal in scope and died with the group. In general, early man lacked a concern for the environment, for the creatures in it and for the consequences of man's activity. Great cities were born in the Mediterranean basin and elsewhere, many to be abandoned in a few hundred years as desolate monuments to man's ineptitude. Climatic change has been proposed as explanation for these early failures of

urban man. The overwhelming weight of evidence, however, points clearly to man, not climate, as the agency that let in the desert, or destroyed the capability of the soil.

Then scarcely a century ago, man turned his talents to vital invention. Aseptic surgery, vaccination, public-health measures, antibiotics and chemotherapy introduced a new era in which man emerged as the first creature to influence directly the answers to the ageless question: Who dies, when, and of what? The outcome of these discoveries is clearly revealed in the burgeoning human populations.

It was the thought processes of science that consolidated the era of vital invention and started man on the harried course to large-scale environmental manipulation. The scientific image emerged, frequently in sharp conflict with the folk image of the living world and its relationships. As Boulding has pointed out, even a relatively imperfect shift from the folk image of man and society to a scientific image involves man in at least two large, irreversible, and related changes. The first of these is the increase in self-consciousness, not only of the individual himself, but also of the society in which he has been placed. The second change is the development of the integrated systems point of view, where the world is seen as functioning in an orderly and predictable way, where imposed changes have predictable consequences.

Man is no longer the frail primate, surrounded on every hand by baleful and mysterious forces, wild beasts and pestilence. He glories in his new capacity to go where he wills when he wishes, to conquer all natural obstacles, to guide his own star. We have man the despoiler, the casual pursuer of short-term goals, the arbiter of survival for so much of the world's biota. At the same time, this is man the creator of majestic works, self-conscious man, the only moral creature, man the conservator ready to answer for his errors and to extend the umbrella of his competence

* Substance of an address delivered at the Bicentennial Celebration held in Washington during September 16-18 to commemorate the birth of James Smithson (see *Nature* of October 23, p. 321).

over many lesser forms of life with which he shares his environment.

This, to me, is one of the great revolutions of attitude of all time; man the fearful becomes man the master.

Roots of Conservation

Conservation as we know it to-day is a complicated and interesting area of activity. In very large part, it is the expression of the enlightened self-interest of a population, arising from the understanding, scientifically gained, of the laws of growth, the known facts of population regulation, and the discovery that, for wild crops, as for time, the environment has a capacity which it cannot exceed, but can sustain.

This is conservation as it is properly applied to the living, self-replacing resources on which man can draw for his sustenance, his energy needs and his economic enrichment. The doctrine of wise use is the operating principle. Properly stated, it is that a living resource may not be used at a rate faster than its capacity to replace itself. Sustained yield is the objective of the management programmes in forestry, in fisheries and in wild-life management. In these areas of conservation, self-consciousness is happily bolstered by the profit motive. It profits man in the long run to conserve the renewable resources.

The evolution of the principle of sustained yield has its roots in the folk learning of antiquity, given form, substance and conceptual veracity by science. It first received public acknowledgement as the operating framework of a national policy when, in 1910, President Theodore Roosevelt promulgated what has come to be known as the Roosevelt Doctrine. This recognized all outdoor resources as an inseparable whole, established a public responsibility for the wise use of these resources and declared science as the working instrument to guide public policy.

But though the Roosevelt Doctrine marked the inauguration of the era of scientific conservation, it was itself the outcome of half a century of struggle acted out in the political arena of the United States, as the old concepts of the private right to all public resources were defeated in the devastated forest lands of America, and the role of water on the arid lands of the central continent became established in law. The names of Carl Schurz, U.S. Secretary of the Interior under President Hayes, and of John Wesley Powell are prominent among those who saw the message of conservation boldly written in a troubled landscape nearly a century ago. But, as usual, reason was slow in acceptance, as its adversary was the easy short-term profit where wealth and political influence were bedfellows.

In almost every instance it was born of human tragedy; ghost towns in a chaos of ravished forest land, towering clouds of top-soil which carried with them the hopes of thousands in Oklahoma and the other dust-bowl areas of the world, surging flood waters on the delta lands, stinking rivers carrying sickness to all who used them. Always the task faced by the ecologist in conservation has been to rescue man from the consequences of ignorance, avarice or folly.

The continent is still repaying the debt which was ruthlessly extracted from the landscape in the nineteenth century. "In the forests, as on the ranges, and in the mines, it was every man for himself, and it would take a generation of protest, and a Rough Rider President, to slow down the onslaught and put the get-rich-quick capitalists on the defensive. The nineteenth century lumber tycoons, to give them full credit, housed a growing nation, cleared land, and hastened the pace of westward expansion. However, they set world records for waste, and their prodigal prosperity consumed the stored capital of Nature—which, by right, belonged to other generations" (Udall, 98, 1963).

The other parent of to-day's conservation takes its origin from more complicated sources: moral conscience offended by killing beyond need, religious concepts of cruelty and a genuine concern to retain for our enjoyment creatures whose beauty of colour, form, movement and sound appeal to the senses and give us pleasure. The protectionist movement has its roots as deep in human antiquity as art, music and religion. In its earliest manifestations, it is a folk movement strongly espoused by an ever-enlarging segment of our society. However, along the way, it is gaining the strength of true understanding derived from scientific inquiry and the unarguable power of the market place. People will pay for it.

This aspect of conservation was at first concerned with the protection of birds by the establishment of refuges, but rapidly broadened to encompass the preservation of entire areas of special beauty or unique biota. The concept of the national park emerged as one of the most powerful popular movements of our time.

Perhaps the dominant trend in conservation to-day arises out of our growing realization of the influence human populations have already had on their environment. If indeed we seek mastery of our fate, it is of fundamental importance to control ourselves and regulate our actions as degraders of the potential contribution that environments may make to future generations. The frontier philosophy of do what most profits without thought for to-morrow is no longer tolerated as a working principle by any advanced society.

It is near 30 years since Aldo Leopold gave expression to the "ecological conscience", recognizing each generation not as owners outright of the land and its resources, but as the holders of life rent with the responsibility of wise custodianship without reduction in potential. Ecologists have been slow to involve themselves with a study of man as the dominant influence in the world's terrestrial ecosystems. But, even so, our knowledge of human ecology is growing rapidly, paced by such exhaustive summaries as the Wenner-Gren Foundation report on *Man's Role in Changing the Face of the Earth* (1956); the searching studies of the British scene by the Nature Conservancy; and the recent conference on the "Future Environments of North America" (1964). As the understanding of the ecologists increases, so also does the appreciation of our potential for actions detrimental to human environment.

The complex web of man's impact on his environment defies neat compartmentalization; but there are five areas that, by virtue of differing group interest and research, need justify separate comment: (1) Soil conservation; (2) The role of man in the survival of the biota or of its productive capacity; (3) The ecology of man-made pollution; (4) The maintenance of natural beauty and the opportunity to relate to Nature; (5) The maintenance of genetic variety and the preservation of opportunity to learn.

Soil Conservation

Here and there in time and location, man has gleaned bits of information on the nature of the soil as he extracted his crops from the arid lands or sought his livelihood on the steepening hillsides of an overcrowded habitat. The great drought period of the 1930's in central North America, however, for the first time found man ready for massive, effective, science-based attack on the soil problems of a continent. The Soil Conservation Service of the United States established under Franklin Roosevelt's administration can fairly claim to have changed the face of a continent in its 30 years of existence. In so doing, it has mustered an understanding and a technical force that is carrying its influence to many lands.

Soil conservation in North America has made possible the tremendous food-producing potential of the continent;

but beyond this it has had immeasurable influence on all other aspects of the conservation of natural resources.

Conservation of Species

The expansion of natural history into ecology during the scientific revolution saw the principles on which the idea of conservation rests added to abundantly, both at the operating level and in concept. The community as a vital entity operating in accord with discernible laws that could yield prediction; the idea of the limiting factor, and of density-dependent feed-back between organism and environment, were among those hypotheses that provided new conceptual equipment.

The idea of altering the natural forces that were regulating the lives of creatures other than ourselves is a major landmark in the flowering of human ideas—its emergence marked the transition between simple protection and management; the purposeful attempt to alter the environmental impact on a species or community to produce a preconceived result. Management includes the regulation of the direct or indirect impact of man on the species or community, as well as all attempts to alter such other features of the environment as water, food, shelter, parasites, disease, predation, special facilities, competition or distribution. The objective of management in conservation to-day is much broader than the mere maximizing of profit. Each living organism is seen as the repository of a unique assortment of biological information gained through the eras via the process of evolution. Each offers a potential enrichment of human knowledge, and enjoyment that is limited only by our capacity to appreciate. The loss of any single element in the world's store of varied life is viewed as an erosion of the quality of the human environment.

In general terms, management is directed to the encouragement of those species we desire to assist, to reduce populations of creatures we regard as damaging our interests or to maintain the integrity of an entire assembly of plants and animals; that is, to maintain a community for its riches of species and associations. Species-oriented conservation falls into three main categories: management for survival; management of distribution; and management for harvest.

Management for Survival

In nineteen hundred years the world has lost 107 kinds of mammals, and close on 100 kinds of birds. The extinction of plants and the lesser animals is not known but probably vastly exceeds that of birds and mammals. Nearly 70 per cent of these losses have occurred in the past century and mostly through the activity of man. Here and there throughout the world, on every continent and on many of the remotest islands a host of other species, more than 1,000 strong, faces the imminence of complete and final passage from the world's fauna.

Extinction has been an essential companion of evolution since the beginning of time, and there is no reason to believe that the process is complete. Nevertheless, it is an ideal of conservation that no creature should pass from the face of the Earth through the instrumentality of man. If we would pose as the masters of creation, to prevent extermination of a large and obvious form of life stands as a challenge to our ingenuity and our competence.

There is an element of drama also in the plight of a vanishing creature which captures the imagination. The challenge to aid the troubled species thus has consequences far beyond the retention of its genotype. It becomes an instrument of enlightenment; thousands of people develop an increased awareness of the principles of conservation through identification with the endeavour.

Several special agencies make their particular concern the assembly of all available data on endangered species. The International Union for the Protection of Birds, the

Survival Service Commission of the International Union for the Conservation of Nature as well as many agencies of Western Governments, Japan and several other nations contribute in important degree to the identification of species in trouble and in co-ordinating assistance programmes. The International Union and the World Wildlife Fund muster the skills and organize the support for emergency attempts to redress the havoc man has wrought on wildlife in the farthest corners of the world. In the United States the recent Land and Water Conservation Fund Act provides for the protection of endangered species there. There are substantial successes, but the tasks are huge and without precedent. Species that are in trouble as an outcome of man's alterations of habitat have proved most difficult to assist, as have insular endemics. Long periods of evolution out of contact with the specialized competitors, predators and diseases of the continents have rendered island species most vulnerable to the impact of man-induced changes in environment. Islands are unique and desperately fragile. They require special care. Introductions of exotics, domestic species, or of diseases are almost certain to be catastrophic.

A recent approach to the restoration of endangered species is through the instrument of captive rearing for later release into the wild. It cannot be regarded as the perfect answer as many species are not susceptible to confined rearing, and others have been shown to possess a heritable factor for wildness which may be selected against in captive breeding.

There are two other potential hazards to releasing hand-reared or even wild-caught stock from elsewhere in an effort to increase the numbers of an insecure population. One is the danger of introducing a different and less well-adapted genotype. The second is the risk of introducing disease organisms foreign to the creature.

An ever-present danger of such programmes of introduction or re-introduction is the loss of the genetic distinction of a local endemic form. The widespread transplanting of such native North American species as bobwhite quail and cottontail is suspected of having changed the genotype of some local forms. On occasion, the hybrid has locked the time-earned adaptive features of the local race, and what started as a logical attempt to aid a struggling population became the kiss of death.

We have slowly learned to appreciate the tolerance developed between disease organism and host during eons of mutual evolution. But experience has been a hard teacher and many an organism has suffered the devastating consequence of either our ignorance or our stupidity as we refused to apply what knowledge we had gained. A case in point can be seen in the plight of the largest wild-living stock of American bison in the world. The transplantation of a disease-ridden herd of plains bison into the last remaining stronghold of the wood bison in Wood Buffalo Park, Canada, led to the predicted but ignored consequences. These may not only finish the race but may see the transmission of the disease into clean stocks of moose and barren ground caribou.

It is impossible to foresee the direction that our interests in the biota will take as human tenure of the Earth lengthens, as our population increases, our demands on the resources expand and our understanding of the environment becomes ever more detailed. To-day our concern is for the forest trees, certain more obvious plants, and for the mammals, birds, some fishes and some reptiles. Our knowledge of the ecological facts pertinent to the management of most of these is inadequate and we are totally innocent of the data which would permit us to manage the populations of most of the living creatures of the world. The only tenable approach to the maintenance of the largest part of the biota is through the management of ecosystems rather than individual species.

Where climax situations are concerned, the task, in theory, is relatively simple. On the other hand, the restoration and maintenance of any of the transitory seral stages

in a living community of plants and animals is a task of great complexity. So much so that we are at present almost powerless to plan for the successful ecological management of even the smaller national parks of America.

The usual approach to the conservation of vanishing plants or animals has been to create a refuge or park to contain it and to exclude fire. Special reserved areas have been established to maintain stands of climax redwood forest, Douglas firs, Monterey cypresses, organ pipe cactuses, Joshua trees and the entire flora of some of the Hawaiian craters. These measures are seldom adequate, and the truly ecological view of the objectives is only beginning to enter into planning and administration.

Management of Distribution

In general, a species becomes less vulnerable as its distribution widens. Of special importance is discontinuity of distribution as this protects against the inadvertent catastrophe that can overwhelm a single small population.

We can sometimes foster discontinuity of distribution by carefully selected transplants of a species into unoccupied but apparently suitable habitat.

This, at the same time, provides a unique opportunity for the establishment of a disease-free nucleus population. Natural extinction has been an active process through all existence. Although we have little knowledge of the causes of extinction, epizootic disease is a possibility. Thus, the establishment of disease-free discontinuous populations should give added survival value to the species and will give additional surety to our objective of management for variety.

Management of Numbers

In general, the utilization of a new element in the biological resource still follows the primitive pattern. Thus, for each new species for which we find a use, there occurs first a period of uninhibited exploitation, as if the resource was unlimited. Sooner or later, declining availability arouses concern that the stock will be commercially eliminated. Too frequently, the rising cash value emerging from progressive scarcity obscures the biological situation and renders politically difficult the establishment of measures adequate to restore the productivity of the resource and to place it on a basis of sustained yield management.

Conservation practices designed to manage for sustained yield consist of fact-finding, restrictive regulation and positive management. The important difference between the last two is that, while restrictive regulation is designed to regulate human exploitation of a wild species to a level at or below the mean replacement rate, positive management is oriented toward increasing the production or survival of young, and to lengthening the life of adults of the managed species. In terms of the classical sigmoid of population growth the objective of conservation of a harvested population is to maintain the population at the level of greatest rate of increase while at the same time moving this upward by raising the ceiling imposed by the environment.

Most wild populations exist within a delicately balanced complex of species that make mutual use of the food potential of the environment. Some competition between species is frequent. The consequence of human depletion of certain species is often to promote a new balance within which the preferred species plays a lesser part. A biological vacuum often does not arise, and for this reason it may be impossible to restore the population to its early productivity even under the best of management.

Where the demand is greatest, the concept of maximum sustainable yield has come into being. This may be expressed in terms of number, weight, or cash return.

The simpler task of sustained yield management is that confronting the forester whose product is wood. His

populations are immobile and easily measured; the regulation of size of harvest presents few biological problems of decision. The unique factors are the long period of growth between harvests and, in the north, the vast areas of almost single species forests. These render protection from fire and pestilence the major hazards to success, and the technology of these tasks becomes limiting.

Increasingly, the value of many forests arises not from their primary product but from their contribution to maintaining the integrity of watersheds, as an environment for wildlife and as a place for human recreation. Here the designation of goals is more difficult, and the knowledge demanded for successful management more precise. In only a few areas is adequate research information available.

Few among the world's fishes provide commercially important harvests and for only a handful of species can it be claimed that effective, sustained yield management is in force. In many instances our biological ignorance is inhibiting the development of management routines. For more of the marine fishes the political complications of the multi-national competition for the crop frustrate the application of even existing information to the task of conservation.

The principle of abstention which is being pioneered with respect to certain of the North Pacific fisheries is a useful experiment in international conservation. Under this Canada, Japan and the United States have agreed to abstain from fishing stocks of fish under full use and scientific management by any one of them. To be effective, however, agreements of this sort require the participation of all those nations that are competing for the fish resource of the management area. An important effect of such an agreement is the incentive for additional studies and better management.

The worst example of the failure of conservation, not for want of biological information but from bad faith, commercial avarice and political iniquity, is to be seen in our treatment of the marine mammals of the world. Completely adequate demonstration has been available for at least a decade that species after species among the larger whales is being reduced to the point of extinction, and the industrial potential of the industry thus destroyed. Despite this, the responsible international organization of whaling nations has been repeatedly prevented from establishing the essential conservation measures through the political influence wielded by certain commercial interests bent only on recouping an investment as quickly as possible.

The harp and hood seals of the North American east coast are among the remaining commercially useful seal populations, and they are suffering a similar fate.

Ecology of Pollution

The most insidious influences of man in the environment arises from the disposal of wastes and from the purposeful distribution of biocide chemicals to destroy plants, insects and related organisms regarded as inimical to certain human activities. These two forms of activity have the common denominator of so altering the environment chemically or physically that it is no longer a suitable habitat for many native forms of life and is often damaged as a habitat for man himself.

Egler (1964) has stated that "the problem of pesticides in the human environment is 95 per cent a problem—not in the scientific knowledge of pesticides, not in the scientific knowledge of the environment, but in the scientific knowledge of human behaviour". It is a combination of apathy and organized stupidity frequently motivated by the market-place. The same can be said for pollution in the more usual sense. The devastating consequences of the ecological ignorance that fosters and permits such action was realistically presented to millions of people the world over by Rachel Carson in *Silent Spring* (1962).

Again to quote Egler: "In general, we have acted with remarkable arrogance to the whole of Nature of which we are a part. Any part we do not want, we seek to destroy, completely and utterly. . . . With the destruction of each such 'pest' by the use of the handiest, cheapest, most quickly acting pesticide, goes the destruction of anything else about which we do not care at the moment, or the eventual destruction of other things about which we may care but by such remote side-effects that the actual connection can be disputed".

The problem is of world-wide scope and increases with the rise of human populations, but is most intense in the sophisticated societies with the most advanced chemical industries.

Despite the growing public awareness that there are grave consequences from our present introduction of destructive chemicals into the ecosystem, the manufacture and distribution of these are increasing annually. There is no limit to our ingenuity in designing new forms in which we can introduce chemicals into the complicated web of our ecosystems, while we are powerless to influence where they will travel and impotent to remove them.

The biological destruction of rivers and lakes through the introduction into them of sewage and the chemical effluent of industry has aroused widespread public concern. The problem has become a national emergency in many countries and has generated powerful corrective efforts. Despite local success, the pollution of fresh waters remains one of the most devastating consequences of civilization.

Nowhere else in our relationship with the biological world in which we live are the lines of our understanding, our communication, our sources of political action, our economic ambitions, our biases, and our fears more hopelessly interwoven. It is difficult not to despair that an economic society is impotent to prevent the pollution of land, air and water which we now support or condone. Viewed the world over, mankind to-day is indeed managing his environment. This management, however, is not the outcome of a studied attempt to proceed toward a desired objective; it is rather the cumulative result of varied extemporizing, unplanned and unco-ordinated, directed toward the satisfaction of the immediate need. Individuals, societies and governments frequently compete and promote conflicting attitudes and acts of strong environmental consequence. We are completely without any well-defined and generally accepted philosophy to direct our specific behaviour toward our surroundings.

Even our governments are not organized to react effectively to a comprehensive management of our actions as they influence the human biophysical environment. We are geared for local crises; the epidemic, the crop failure, the forest fire, the devastation of riparian lowlands by flood, all trigger prompt action by some appropriate authority. These are crises easily seen and understood, dramatic in their impact on our immediate desires. The environmental changes of the greater ultimate importance take place so gradually, insidiously, unobtrusively that they escape our attention until irreparable harm is done. Cumulative contamination of the environment by the waste products of our factories, kitchens and bathrooms; gradual destruction of wild-life habitats with all they contain; the sprawling blight that flows from our cities farther and farther into the countryside; the indestructible wastes of our technology that beer can after 'auto-carcass', plastic bottle after 'pliofilm' bag spread filth over our beauty spots, these have not yet reached that point in public understanding where consensus can lead to effective corrective action.

Man and the Enjoyment Resources

The world of to-day falls, perhaps loosely, into two categories of human societies. There are those which, despite improvements in scattered technologies, are concerned, at the level of the average individual, with the

day-to-day task of staying alive. For them, it can be truly said that the immediate objectives and concepts have changed little since the days of human origin. The concern is living, not the quality of life. At the other extreme are those fortunate societies that have evolved through science and social ingenuity a competence that has to a very large extent banished the folk fears of starvation and pestilence and introduced new horizons to the image of life. Concern has shifted to the richness of experience that any individual can expect from his environment. It has become a proper objective of all mankind to equalize, as far as possible, the opportunity available to all individuals in all societies. There is no gain for man, however, if equalization is downwards.

The logical concomitant of this principle is that those societies that have progressed farthest in the search for quality of living should exercise a concern extending far beyond their borders. Mankind's to-morrow will be found on the world scene, not within the parochial confines of a contemporary political unit. The contribution to the food stocks and to the economic potential of a country that is to be found in its renewable consumptive resources makes these obvious first candidates for attention. But, Sir Julian Huxley has so well said: "Human ecology involves finding out what resources are available in our environments and how to make best use of them. We have to think first of all of the material resources—minerals, water power, soil, forests, agricultural production—but we must also think of the non-material or enjoyment resources of the habitat, such as natural beauty and solitude, interest and adventure, wild scenery and wildlife.

"We should set about planning a Fulfilment Society rather than a Welfare Society, an Efficiency Society, or a Power Society."

It can safely be said that one of the important criteria of an advanced society is its devotion to the maintenance of the ecological well-being of the human environment in all its attributes. Prominent among these will be the non-consumptive uses for recreational enjoyment and scientific enrichment.

The recognition of the deep need of man for opportunity to associate himself with Nature first occurred as a revulsion from the stark surroundings of the factory environment which became the lot of the majority during the Industrial Revolution. The easily accessible commons, though not then recognized as such—for psychiatrists were as unknown as jet propulsion—became psychiatric safety valves for the toiling thousands of Britons.

A century ago, the land-grabbing aristocracy of Britain, who had already taken to themselves one acre of every seven in the nation, attempted to enclose Wimbledon and Epsom Commons. This was the touchstone to a legal battle of classical import. Henry Fawcett, M.P., and professor of political economy in the University of Cambridge, championed the cause and saw in it the great principle that was at issue—the public right to open space reserved in its name. The legal battle was fought between the Corporation of London and fourteen lords of manors who sought to divide Epping Forest. The Corporation won the suit and established the all-important legal principle on which so much of our more recent conservation legislation has rested. The Act of 1876 permanently declared in Britain the public interest in open spaces as taking precedence over private desires. Since 1925, British law has given to the public a statutory right of access for air and exercise on every common or place of manorial waste and to any rural common (Gibson, 1964).

An ocean away, the practical dreamers of the New World were forming ideas of similar philosophy. With the expansiveness of thinking that accompanied the great spaces, American concepts spread from such fine civic beauty spots as New York's Central Park to California's Yosemite and the magnificent two million acres of the first National Park—Yellowstone: all this before 1870.

The first voices also were decrying two and a half centuries devoted to plundering the natural resources of North America. The buffalo herds were gone, as were the vast flocks of passenger pigeons; but worse, none had successfully challenged the view that the natural wealth of the biological resources was free for the taking; the continent's devastated forests were prime testimony.

It took the combination of a brilliant, visionary forester, Gifford Pinchot, and Theodore Roosevelt, a president of the United States with deep roots in the wilderness, to turn the tide and to introduce the concepts of conservation. Among the first large-scale tangible results was the establishment of the great National Forest system of the United States. Designed to produce timber for the long-time good of the nation, these forests now contribute richly to the recreational lands of the continent. None in the new world could then foresee the crowded cities, the airports, super-highways, the clatter, speed and tensions to come, and the desperate need of people to find themselves again in the impersonality of unspoiled landscapes, in the surging vitality of many small lives.

"Modern man is turning almost instinctively to the last remnants of the primeval scene, to know again the mystery of the unknown and the beauties of unchanged terrain. While it is doubtful if his ancestors appreciated the intangible qualities of wild country, he is developing that capacity. Now that wilderness is no longer a threat to security or survival, he is beginning to look at it for the first time with some measure of appreciation and understanding, realizing that within it may be the answer to confusion and a source of inspiration closely allied to beauty. . . . National Parks, as reservations of beauty, are sanctuaries where people may recapture, at least in part, some glimmer of the visions that may have stirred their forebears" (Olson, 1962).

With pathetic frequency our groping hands have left irreparable scars on the beauty we sought to serve. Super-highways, garbage dumps, hydroelectric impoundments, mining and deforesting (cattle grazing), are only a few of the incongruous and destructive activities we have condoned in our parks, but we have hammered out some principles along the way.

(1) On the world scene the national park concept has usefully served many objectives. The most frequent has been the preservation of endangered species where this depends on intact segments of entire ecosystems. A new and exciting concept has emerged on the American continent. National parks, as we now view them, may have great value as museums of ecology, as wild-life reserves, archaeological sites or for the protection of natural wonders, but their first function is to provide the setting, the beauty, timelessness and natural order in which man can regain the perspective he needs.

(2) The national parks belong to all people and no part of the policy that guides their operation should be oriented to provide private profit to local residents.

(3) An attested ecological objective to guide park policy is essential. The Leopold Committee urges that this be to retain or restore the ecological conditions obtaining when the region was discovered.

(4) Protection of park values from increasing hordes of users is among the most challenging problems to-day. Zoning for quality of use and the limitation of access are growing necessities.

(5) The social organization requisite to the protection of State or Provincial parks whose policy and survival can be altered on executive whim has so far eluded our political ingenuity. On the American continent, where the political voice of the *entrepreneur* is loudest, the integrity of all parks required the constant vigilance of militant citizen groups.

(6) For the economically oriented, it has been shown beyond doubt that well-mannered national parks pay dividends beyond their operating costs and may, as in parts of Africa, form the basis of a major industry.

At this point, the conservation road forks again into the scientific and the aesthetic. With or without our consent, the evolutionary process will continue, new forms will arise and others vanish, most of them without our ken. The advent of man introduced a new and dominant force into the biosphere. By his selection as by his modification of the environment he has greatly altered the *tempo* and nature of evolutionary change. It is certain that the practical consequences of the revolution in biology will further increase our capacity for positive influence in the evolutionary process. But this does not mean that we should ignore the challenge to interfere with the consequences of our actions or even to deny to Nature the right to extirpate. The world's store of genetic material is seen as an inexhaustible source of novel combinations which can be used for the future benefit of man. Each genotype lost before evolution has replaced it is another step in the degradation of our environment. This is an expression of our pragmatic concern with conservation.

The ecologist sees yet another reason for attempting to preserve intact samples of the various biotic communities.

The task of extracting the ecological truths is far from complete and new techniques offer constant new opportunities to search more deeply. Lost segments of the ecosystem take with them their unexposed truths. Our opportunity to learn and to understand is permanently impoverished. Strong reasons, therefore, can be advanced for conserving segments of all major communities for the sole purpose of research.

In the other direction, it is being ever more emphatically asked why man should have to seek beauty only in far places. There is creative capacity in man that, if given full rein, could replace much that is sordid and ugly in our urban environment with beauty, clean air and green space.

As the history of this age is written, conservation as a concept will be regarded as perhaps the greatest contribution of the New World to human ideas. For the idea had its birth and saw most of its evolution in the United States of America. In a century Powell's vision of sustained-yield forestry spread and adapted to encompass human contact with the entire living world. It gained depth of perception and an almost religious fervour from the Marshs, Muirs and Thoreaus, and scientific rationale from the host of naturalists and ecologists that have emerged from the universities of the northern hemisphere. It provided the banner around which rallied all those whose vision of the man at his finest involved a sensitive integration into the biophysical world. The Sierra Clubs, Audubon Societies, Wilderness Societies and Unions for the Conservation of Nature have given power to the cause without which the concept could not have found political and physical expression.

But the cause is far from won, and at an increasing rate the twin forces of a burgeoning technology and a surging human population are posing ever more difficult problems for the conservators to solve. At an increasing rate we pollute the land, the air and the sea, convert our rivers into sewers and spread our indestructible wastes along the remotest shores. An urgent challenge to our ingenuity is the disposal of our wastes.

Over vast areas of the world even the most elementary conservation concepts have still to penetrate. Here fire and destructive agriculture rapidly narrow the gap between man's numbers and his food supply; balanced ecosystems are degraded to uselessness, biotas vanish for ever.

We have not even approached the fascinating, but vital, problem of man in an enclosed ecosystem. In a very real sense we are denizens of a space capsule to which nothing enters but solar energy. What population of men will the renewable resources of the world support? At what level does the addition of another million reduce rather than increase the quality of human life? These

are questions as close to the core of morality as to conservation. To attack them at all demands the attention of the finest ecological, sociological and political minds we can muster. The answer is urgent, as each passing decade brings us either further on the down grade or nearer the asymptote. We know not which.

It has been relatively easy to find support for conservation on the American continent, where our man-to-space ratio has been low, hunger has not been an alternative where an acre was allocated to quality of living rather than to food for survival, and where the economic advantages were obvious. The pressures will change as the alternatives gain more immediacy.

Central to conservation on this continent is the gradual change in the legal view of the rights of the individual in relation to the long-term benefits to society. In this context certain recent interpretations of the Supreme Court of the United States of America have the greatest significance. That the individual as a member of a society retains only those liberties specifically allocated to him by the society is an interpretation with broad impact in the natural sense. There still remains in many quarters, however, the narrow interpretation that only consumptive use is really use and should take priority in competitions. There is the demand also that even the aesthetic qualities of our lives

should be justified in dollar values when alternative uses of land are an issue. Conservation lives in both our worlds, the economic and the aesthetic; the contribution of the ideology is equally to both, but the standards of comparison are probably invalid.

It is the unique revelation of man that he is not only consciously sensitive to his own environment, but also relates himself to much larger and more complex processes in which he plays a part. His image of the world then becomes an important element in the processes of the world itself.

A central element in our vision of the kind of world we would inhabit is the ideology of conservation. Within it we find values that we will defend and ideas that we seek to propagate. Man has come full circle from the unwilling participant in the processes of survival to become the only creature whose vision influences those processes. Conservation and other ideology have played so important a part in human affairs and hold so much for man's future.

Even in those unfortunate areas of our own land and others, where avarice and ignorance still triumph, the achievements and ideals of conservation stand as a constant reminder of what could be. Self-consciousness once awakened can no longer be escaped.

OBITUARY

Academician Eugene N. Pavlovsky

THE death of Eugene Nikanorovitch Pavlovsky on May 27, 1965, in his eighty-second year, deprived Soviet science of one of its most eminent representatives, who dominated the scene of medical zoology in his country for more than half a century and whose outstanding contributions in the field of biology and parasitology found recognition throughout the world.

E. N. Pavlovsky was born on March 5, 1884, in the town of Birjutch, Voronezh Province. After receiving his secondary education at the Borisoglebsk Gymnasium, where he gained a gold medal on matriculation in 1903, he was admitted to the Military Medical Academy of St. Petersburg. Though primarily intended for the training of army doctors, the Academy was—and still is—one of the greatest medical schools in Russia, where young Pavlovsky studied under some of the most renowned medical scientists, including I. P. Pavlov, the physiologist, A. A. Maximov, the histologist, and N. A. Cholodkovsky, the zoologist.

Pavlovsky showed an early interest in zoology, and while still a student he started the research work in the laboratory of Prof. Cholodkovsky on the anatomy of lice and on the poison glands of arthropods and fishes, for which the Academy awarded him a gold medal. On graduating with distinction in 1909, Pavlovsky was appointed assistant to his teacher, N. A. Cholodkovsky, and in 1913 he took the M.D. degree with a thesis on the structure of poison glands in arthropods, and was elected Privat-docent. The first period of Pavlovsky's scientific career was devoted mainly to investigations on venomous animals, for the study of which he devised refined methods of manual dissection, described in a series of handbooks and recently in *Methoden der Sektion von Insekten* (Berlin, 1960). The results of some of this work were incorporated in his M.Sc. thesis of the University of Petrograd, and eventually in an important monograph on venomous animals published in Germany (1927).

In the meantime, on the death of Cholodkovsky in 1921, Pavlovsky succeeded him as professor of biology and parasitology (as the chair was renamed). During this period, the upheaval caused by the First World War

and then by the civil war brought about an aftermath of pandemic outbreaks of malaria, typhus and other infectious diseases which were ravaging the young Soviet Republic. Pavlovsky responded to the urgent necessity of dealing with the disastrous situation by directing all his energy and knowledge to problems of public health, thereby initiating the second, and most fruitful, period of his scientific activities, to which he dedicated the rest of his life. From 1928 onwards Pavlovsky and his teams carried out more than 160 parasitological and epidemiological surveys throughout the U.S.S.R. These expeditions revealed a close connexion between diverse arthropod-borne infections of man and lower mammals, which were shown to be zoonoses (for example, seasonal encephalitides, relapsing fevers, leishmaniasis), and laid the foundation, in 1939, of the concept of natural foci (or focality) of transmissible diseases, which was Pavlovsky's most outstanding achievement.

He demonstrated that some of these diseases are naturally localized in foci within well-defined geographical areas (biotopes), where the pathogenic organisms, their vectors and hosts form an ecological association (biocenose) within which the infection circulates for indefinite periods of time from donor-hosts via vectors to recipient-hosts—represented by wild animals—quite independently of man. It is only when human beings intrude on such an enzootic locality or settle down to live there that they expose themselves to the attacks of the vectors, which then transmit to them the parasites acquired from the wild reservoir hosts. On the basis of this discovery, Pavlovsky formulated his idea of "landscape epidemiology": since natural enzootic foci are characterized by definite geographical peculiarities of the terrain, these can serve as indicators of the presence in a given area of certain diseases presenting a potential danger to man. The examination of the geographical background of zoonoses enabled Pavlovsky and his associates to detect and control numerous foci of human infections within the Soviet Union. It has also inspired a great volume of epidemiological investigations throughout the rest of the world. The recognition of its importance is reflected in the creation of centres for the study of zoonoses in South America, the United States and East Africa, as well as at the World Health Organization.

To Pavlovsky also belongs the credit of developing an ecological approach to the phenomenon of parasitism, based on the recognition of the organism of the host as the environment of its parasites. He introduced the original concept of parasitocenoses, concerning the mutual relations between the components of the parasitic fauna of a host. One of the great merits of his scientific activities was the application of scientific principles to the solution of problems of practical importance in public health, which resulted in the local eradication of certain diseases. Pavlovsky was the author of more than 1,000 publications, devoted to parasitology, entomology, microbiology, epidemiology, toxicology and evolution, as well as to the history of biology and medicine, and including several monographs and text-books. Some of his most important works have recently been brought together in three volumes (in Russian): *General Principles of Parasitology and Zoology* (1961); *Collected Papers on Experimental Zoology and Toxic Animals* (1963); and *Collected Papers on Experimental Parasitology* (1963), as well as in the following English versions: *Human Diseases with Natural*

Foci (Moscow, 1963) and *Natural Nidality of Transmissible Diseases, with special reference to the Landscape Epidemiology of Zoonanthroposes* (in the press: U.S.A.). Pavlovsky was also an outstanding teacher, who created an imposing school of Russian parasitologists.

In addition to the professorship at the Military Medical Academy, which he relinquished in 1958 with the rank of Lieutenant-General in the Soviet Army Medical Service, Pavlovsky was for many years director of the Zoological Institute of the Academy of Sciences and president of the Geographical and Entomological Societies of the U.S.S.R. He was also an honorary member of several academies of science and of numerous learned societies outside his own country. For his outstanding scientific achievements he was elected a member of the Academy of Sciences in 1939 and of the Academy of Medical Sciences of the U.S.S.R. in 1944; he was awarded the honorary degree of D.-ès-Sc. of the Sorbonne, and was the recipient of many prizes and medals, including the Darwin-Wallace Medal of the Linnean Society in 1959.

CECIL A. HOARE

NEWS and VIEWS

Civil Engineering in the Welsh College of Advanced Technology, Cardiff: Prof. J. D. Geddes

DR. J. D. GEDDES, senior lecturer in civil engineering materials in the University of Newcastle upon Tyne, has been appointed professor of civil engineering in the Welsh College of Advanced Technology, Cardiff, from January 1. Dr. Geddes gained a first-class honours degree at the University of Newcastle upon Tyne in 1949. Later, after work with consulting civil engineers, he returned to his *alma mater* to work on the subject of piled foundations; he was awarded a Ph.D. for this work at the age of twenty-five. His research was carried out under the Radley postgraduate studentship of the Institute of Civil Engineers, of which body Dr. Geddes already held the distinction of a Miller Prize. In later years he was to be awarded prizes and a Bronze Medal by the Institution of Structural Engineers for his work on mining subsidence. After a year or two as head of the Federal Laboratory of the Public Works Department of Nigeria, controlling all testing and site investigation, he again returned to the University of Newcastle upon Tyne and, for the past 10 years, has been head of the Materials and Building Science Division of the Department of Civil Engineering in the University. His researches have covered mining subsidence and its effects, heat flow through concrete, stresses in buried pipelines, the part played by grout in pre-stressed concrete construction, and studies in site investigation. Dr. Geddes has controlled an effective testing laboratory run by the Department as a regional service, and has forged a bond between the profession and the University. He has found time to become an authority on the history of the British regiments and will return in the spring to give a University lecture on the subject in Newcastle. His new students will also welcome his contributions to *Problems in Engineering Soils*—a text-book soon to be published under joint authorship.

Fast Reactor Agreement

THE United Kingdom Atomic Energy Authority and Aktiebolaget Atomenergi, Sweden, have concluded an agreement for exchange of information and collaboration on fast reactor research and development. Information to be exchanged concerns design and operating experience from research and experimental reactors, basic physical and chemical properties of materials for use in fast reactors

and reactor physics, as well as operating experience with certain fuels. The agreement will be effected by means of reports and visits. There may be exchanges of staff from time to time. The progress of the agreement will be reviewed periodically at meetings between representatives of the Authority and Aktiebolaget Atomenergi.

Ministry of Technology

IN written answers in the House of Commons on November 30, the Minister of Technology, Mr. F. Cousins, listed sixteen projects on which he had required the Atomic Energy Authority to carry out research at estimated costs varying from £500 to £73,000 during the financial year 1964-65 and totalling more than £377,800. These projects involved 108 people full-time or part-time, and accounted for about 1 per cent of the Authority's effort on civil research and development in 1965. In addition, work on some minor projects had been authorized, and certain preliminary investigations were being made, while Aldermaston was undertaking non-atomic work on repayment for Government departments, mainly in the defence field, to the amount of about £600,000 in the present year. Desalination research, to the extent of £278,000, was proceeding at Winfrith, Culcheth, Harwell and Risley; work is also under way on hydrostatic extrusion (£54,000) at Springfields, on a medical centrifuge (£15,000) at Capenhurst, and on a design study for scientific payload for the European Space Research Organization satellite (£41,000) at Culham and Aldermaston. The Authority's expenditure on civil nuclear research and development is given as £47.9 million. Of the £35 million shown in the Authority's civil trading account as the proceeds of sales for the year ended March 31, 1965, 60 per cent is attributed to fuel elements for civil reactors, 20 per cent to electricity and 6 per cent to radioactive isotopes. Of the £6.5 million expenditure on the Ministry of Technology in the past 12 months, £4.5 million was for research stations, just under £2 million on grants for research to research associations and other bodies, and £650,000 on the Ministry's headquarters. Appropriations in aid amounted to £850,000.

Mechanical and Electrical Engineering

IN a written answer in the House of Commons on December 1, the Prime Minister, Mr. H. Wilson, stated that the Ministry of Technology would now assume responsibility for sponsoring the mechanical and electrical

engineering industries as a whole, as well as for engineering standards. On these, it would deal direct with the British Standards Institution, but it would not deal with the Institution's work on consumer protection. It would also take over from the Board of Trade the responsibility for determining standard weights and measures. The central co-ordination of measures to promote the growth of industrial productivity, through the National Economic Development Committees and by other means, was a primary concern of the First Secretary of State and Secretary of State for Economic Affairs, but departmental Ministers carried direct responsibility for encouraging productivity in those industries which their departments sponsored. The Minister of Technology would, accordingly, have this responsibility for the mechanical and electrical engineering industries. The Board of Trade would continue to deal direct with these industries on exports, commercial relations and on its other functions and responsibilities which affect industry as a whole.

Scottish Hydroelectric Schemes

IN a statement to the House of Commons on November 29, the Secretary of State for Scotland, Mr. W. Ross, said that he had completed his study of the report into the Enquiry into the Fado-Fionn and Laidon hydroelectric schemes. The report concluded that neither scheme was needed, at least up to 1975, because adequate capacity would be provided by large new stations which must be commissioned by that time elsewhere in Scotland. These would provide power at a lower cost than either of the projected schemes. The assumptions on which these schemes were assessed are subject to change with economic circumstances. Other factors affecting the pattern of electricity generation might also arise out of the continuing development of methods of generation and the fuller exploitation of pumped storage. While, in the light of the report, Mr. Ross was not prepared to confirm the schemes now, he did not regard this as precluding their reconsideration in the future, and when more information was available about future generation plans the North of Scotland Hydro-Electric Board would be free to submit them again.

Colour Television

IN a written reply in the House of Commons on December 1, the Postmaster General, Mr. W. Benn, stated that the Television Advisory Committee had recommended to him that colour television be introduced on 625 lines only, using the PAL system of transmission, and that he was now considering this advice.

British Government Aid Overseas

IN reply to questions in the House of Commons on November 30, the Minister of Overseas Development, Mrs. B. Castle, said that we had now reached the second year of the arrangement under which the British Government contributed £250,000 a year for three years to the recurrent costs of University College, Salisbury. Since the College provides higher education for students of all races in Rhodesia, and operates under Royal Charter, the Government had decided to continue its assistance to the College so long as it is satisfied that conditions continue to exist under which the College is able to discharge this function. If it became clear to the Government that the multi-racial function of the University was being undermined, the Government would reconsider the allocation of aid. British Government contributions in 1964-65 of £6.5 million to the International Bank for Reconstruction and Development, £5.1 million to the International Finance Corporation, £45 million to the International Development Association, £22.7 million to the United Nations Expanded Programme of Technical Assistance and Special Fund, £31.3 million to the United Nations Relief and Works Agency, £3.1 million to the United

Nations Children's Fund, £10.1 million to the United Nations Korean Reconstruction Agency, £1.5 million to United Nations Assistance to the Congo, £1.2 million to the World Food Programme and £11 million to the Indus Basin Development Scheme, brought the total contributions to multilateral agencies since 1946-47 to £137.5 million. Official aid and private investment in developing countries amounted to 1.1 per cent of Britain's gross national product in 1954.

The Bodleian Library

THE annual report of the Curators of the Bodleian Library for the year ended July 31, 1964, notes an overall increase of 10,000 on the previous year's figures for issues of books and manuscripts to readers and staff, while an increase in the number of newly admitted readers was almost wholly in those who were not members of the University. The ratio between members and non-members, for long steady at 3 : 1, is now almost 5 : 2 (University of Oxford. Pp. 28. Supplement No. 9 to the *University Gazette*, August 1965. Oxford: The University, 1965. 2s. 6d.). Besides lists of publications by members of the staff during the year, the report refers to the work of the Department of Western Manuscripts and to that of the Department of Printed Books, where accessions totalled 56,244 volumes and 110,330 parts, compared with 44,826 and 121,276, respectively, in 1962-63; 293,909-microfilm exposures, 16,460 photostats and 712 bromide prints were made from library material and from manuscripts deposited for the purpose.

Lord Nuffield's Benefactions for the Advance of Medicine

THE *Report for 1963-64* of Lord Nuffield's Benefactions for the Advance of Medicine (University of Oxford. Pp. 28. Oxford: The University, 1965) includes lists of staff and publications by the Department of Clinical Medicine, the research interests of which are in gastroenterology, haematology and population pathology. Other Departments, the publications of which are listed, include Surgery, Obstetrics and Gynaecology; Anaesthetics; Orthopaedic Surgery, Pathology, Clinical Biochemistry, and the Nuffield Institute for Medical Research. Research projects in these departments are also briefly listed.

Soils and Foundations

AN important application of soil research concerns the behaviour of soil particles under the influence of loading, and a recent publication, entitled *Soils and Foundations: 1 (Building Research Station Digest (Second Series), No. 63. Pp. 6. London: H.M.S.O., 1965. 4d.)*, deals with the numerous factors that interact with each other and must be kept in mind in building-design. The movement of water in the soil is determined by its texture and by the pressure exerted by a foundation load. Shrinkage and swelling may operate simultaneously, as when structural load is equal to weight removed in excavation. Settlement of the load is rapid on sands but may continue for many years on clays. The differences in settlement between strips, rafts and piles are discussed. Attention is also directed to shrinkage and swelling brought about by rainfall and vegetation and removal of trees on a building site, and the tendency for outside walls to move and produce cracks. Other matters dealt with include peat soils, made-up ground, frost heave and 'quick-sand' conditions.

Timber as Building Material in Hot Climates

THE behaviour of timber used as a building material, under what may be called 'aggressive' environmental conditions, has long been a matter of discussion and practical importance; it is a subject of almost endless research. In Africa the effects of climatic extremes on

timber have engaged the attention of Dr. A. J. Du Toit, research officer, Timber Unit, South African Council for Scientific and Industrial Research, Pretoria, who has published a paper, *The Use of Timber as a Building Material in Hot Climates* (National Building Research Institute. Reprinted from *RILEM Bulletin* No. 25, December 1964. Council for Scientific and Industrial Research. Ref. No. RU I.13). Dr. Du Toit points out that, in Africa, two types of hot conditions can be distinguished, the arid hot type, such as is encountered in the region between Timbuktu and Agadès, and the humid hot type in the region between Douala and Abidjan. The average temperature in both these regions is approximately 80° F, while the average humidity is approximately 35 per cent in the dry region and 83 per cent in the humid region. Obviously wood, being a hygroscopic material, will react quite differently in these contrasting climates. The theme of this paper is that wood can only give satisfactory service as a building material if its properties and behaviour in varying circumstances are known and well understood. There exists a certain amount of prejudice against the use of timber as building material in tropical countries, but this may be partly due to lack of knowledge of its reactions in such environments on the part of builders. It is considered that correct application of present-day knowledge of the properties and behaviour of various woods under tropical conditions would do much to overcome this prejudice. Such information includes primarily climatic agents: the effects of temperature, humidity, rain, exposure to sun, evaporation, dust storms, cyclical influences, maritime influences, direct effects of sea-water (continuous or alternating immersion), saline atmosphere, spray; and biological agents: cryptogams (rot, mould, algae, lichens, fungi), insects (termites, borers, etc.), and vegetation. Dr. Du Toit discusses all these agents, and his paper contains much practical advice on ways and means of protection of timber exposed to these potentially destructive forces, including notes on various West African woods considered to be resistant at least to some of them.

Progress in Protozoology

THE second international conference on "Protozoology", held in London during July–August 1965, discussed many aspects of this subject. Protozoologists the world over will welcome the publication of abstracts of the many papers read at the Conference, entitled *Progress in Protozoology (Abstracts of Papers read at the Second International Conference on Protozoology, London, July 29–August 5, 1965)* (International Conference Series, No. 91. Pp. 278. Amsterdam, New York, London, Milan, Tokyo and Buenos Aires: Excerpta Medica Foundation, 1965. 65s.). Prefaced by a message of welcome and goodwill from Prince Philip, the volume discusses so many aspects of the biology, morphology and ecology of a wide variety of Protozoa that it is impossible to summarize its contents in a brief note. An idea of the number and variety of the papers read may be gained from the fact that the index of authors belonging to many nationalities covers two pages, each with four columns of names.

Antimalarial Prophylaxis in Eastern Nigeria

EVERYONE concerned with the world-wide campaign against malaria, a disease that was once aptly described as 'public enemy No. 1', will be interested in Dr. Hay Arthur's account of antimalarial prophylaxis in primary schools in Eastern Nigeria (*Antimalarial Prophylaxis in Primary Schools in Eastern Nigeria*. February–March, 1965. Pp. 41. London: Wellcome Museum of Medical Research, 1965). Dr. Arthur shows that in the suburbs of a town in Eastern Nigeria, where one out of every two children is infected with malaria, the number of children suffering from the disease can drastically be reduced by a regular weekly dose of 'Daraprim'.

Human Intelligence

SOME reasons why the evolution of human intelligence should be a continuing process have been described by Prof. Sheldon C. Reed, director of the Dight Institute of Human Genetics at the University of Minnesota. When parents' income, education, social status, or I.Q. is correlated with the number of children they produce, correlation coefficients are obtained which are negative in sign. These well-established negative correlations are statistically biased and seriously misleading, because they ignore the important segment of the parental generation which had no children. The negative correlation (-0.30 ± 0.02) between family size and intelligence of the children in it has no meaning for the next generation because the mentally retarded children will have little income, education or social status; they will seldom marry or have offspring. The mentally retarded who do produce may have large families, but the average number of children produced by the retarded is lower than that of normal persons. It is impossible to determine what is happening to the intelligence of mankind as a whole, but it is clear that it is not decreasing at an appreciable rate. Prof. Reed's main conclusion is the perhaps euphoric concept that genetic orthoselection for higher intelligence is continuing at the present time. The challenge of a complex world, with an ever greater premium placed on higher intelligence, should result in an acceleration of the rate of evolution toward that end (*American Scientist*, September 1965).

International Commission on Zoological Nomenclature

NOTICE is hereby given of the possible use of its plenary powers by the International Commission on Zoological Nomenclature in connexion with the following cases, full details of which will be found in the *Bulletin of Zoological Nomenclature* (22, Part 3; November 2, 1965): (1) Suppression of *Drassus atropos* Walckenaer, 1830 (Araneae). (2) Validation of *Pan* and *Panthera* from Oken, 1816 (Mammalia). (3) Neotype for *Ceratophyllus soricis* Dale, 1878 (Insecta, Siphonaptera). (4) Suppression of *Euclidaris* Pomel, 1883, *Papula* Bayle, 1878, *Cidaritis papillataconoidea* Parkinson, 1811, and *Cidaritis savignyi* Audouin, 1826 (Echinoidea). (5) Type-species for *Phasia* Latreille, 1804 (Insecta, Diptera). (6) Suppression of *Papilio lintingensis* Osbeck, 1765 (Insecta, Lepidoptera). (7) Type-species for *Monopsyllus* Kolenati, 1875; suppression of *Geratopsyllus sciuri* Kolenati, 1856, *Monopsyllus sciuri* Kolenati, 1857, and *Ceratopsyllus monotenus* Kolenati, 1856 (Insecta, Siphonaptera). (8) Type-species for *Stizus* Latreille, [1802–1803] (Insecta, Hymenoptera). (9) Type-species for *Diodontus* Curtis, 1834 (Insecta, Hymenoptera). (10) Type-species for *Trychosis* Foerster, 1868 (Insecta, Hymenoptera). (11) Type-species for *Prospaltella* Ashmead, 1904 (Insecta, Hymenoptera). (12) Suppression of *Mullus auriflamma* Forskal, 1775 (Pisces). (13) Type-species for *Chamaemyia* Meigen, 1803 (Insecta, Diptera). (14) Suppression of *Xyleborus* Bowdich, 1825 (Insecta, Coleoptera). Any zoologist who wishes to comment on any of the foregoing cases should do so, in writing, within five months, to the Secretary, International Commission on Zoological Nomenclature, c/o British Museum (Natural History), Cromwell Road, London, S.W.7, England. Those received early enough will be published in the *Bulletin of Zoological Nomenclature*.

Selective Control of Weeds in Rice Fields

IN vast areas of the world, rice is the basic food crop. There are as many different varieties of rice as there are different ways of growing it; but wherever it is cultivated, weed control has always been, and still is, a primary concern of the rice grower. The most universally prevalent and troublesome weed to contend with in rice fields is what is known as barnyard grass; this is so much like rice that even experienced farmers find some difficulty in

distinguishing one from the other in early stages of the growth of the plant. Until comparatively recent times, traditional methods of weed control in rice fields were hand-weeding and flooding; herbicides were tried, but it was found that many of these, which were effective with barnyard grass, had the unfortunate side-effect of also killing the rice. A few years ago a remarkable, highly selective post-emergence herbicide for use on rice was developed by Rohm and Haas known as 'Stam F-34' (3',4'-dichloropropionanilide); this compound is unique in its selective activity in rice; it kills grasses and broad-leaf weeds, but not the rice. An illustrated article in *Rohm and Haas Reporter*, entitled "How Stam Works", explains the facts (23. No. 3; May-June 1965. Rohm and Haas Company, Philadelphia, Pennsylvania; Lennig Chemicals, Ltd., London, W.C.1). 'Stam' is supplied as an emulsifiable concentrate; after dilution with water, this herbicide is applied as a spray, generally by aerial means. The mechanism by which this product operates is briefly and technically described: simply stated, 'Stam' is deactivated by an amazing enzymatic system in rice; barnyard grass and other weeds infesting rice fields are not able to protect themselves, so they wilt and die, and the rice flourishes. The contrast between a field treated with this product and an untreated plot is strikingly shown in one of the coloured photographs illustrating this article; in sprayed fields, the mature rice crop is seen as a clean stand of golden, rice-laden heads; untreated fields are described as "splochy with green and brown—with weeds often choking out the rice plants". It is claimed that when 'Stam' is properly applied to a grassy rice field a substantial increase in yield and a finer quality of rice may be expected.

University of Oxford: Vice-Chancellor's Oration

THE Vice-Chancellor's Oration, which prefaces the annual report for 1964-65 in Supplement No. 3249, of October 1, 1965, to the *Oxford University Gazette* (University of Oxford. Oration by the Vice-Chancellor and Annual Report, 1964-1965. Pp. 37-56. Supplement to *Oxford University Gazette*, No. 3249. Oxford: The University, 1965. 2s.) emphasizes the value of the work of the Franks Commission and refers also to the appointment of a Committee on University Libraries under the chairmanship of Mr. R. Shackleton. The annual report, besides noting the appointment of this Committee, refers also to the creation of new graduate societies and to entitlement to fellowships as recommended by the Norrington Committee and to grants from the Common University Fund to the poorer colleges. Matriculated students in residence increased by 487 on the corresponding figures for 1963-64. Candidates entered for the Final Honours School in engineering numbered only 50 compared with 72 in 1963 and 62 in 1964; for physics, the corresponding figures are 140, 135 and 159, respectively; for chemistry, Part I, 180, 141 and 165; for chemistry, Part II, 147, 130 and 115; for biochemistry, 14, 17 and 18; and for mathematics, 130, 91 and 117. An additional £70,000 was made available to departments for 1964-65 over and above normal growth in expenditure on salaries, including about £28,000 for new proposals. Most of this went to the creation of 16 new posts of lecturer status, 5 in physical sciences and 2 in biological sciences, and 5 faculty lectureships. A new Diploma in the Science of Materials has also been introduced.

Royal Society of London: Montague Napier Trust Fund

THE Council of the Royal Society has accepted the offer by the Trustees of the late Mr. Montague Napier, one of the pioneers of the motor-car and aeroplane engine industry, of a capital sum of the order of £275,000. A new trust fund will be formed with this sum, the income from which will be used for research, with the view of ascertaining the cause of cancer, including any corresponding or allied disease and the means of its preven-

tion, cure and alleviation. In accordance with the wishes of the Trustees, the income from this Montague Napier Trust Fund for the first five years will be transferred to the Institute of Cancer Research for the purpose of developing the bridge of collaboration, which already exists between the Foyal Marsden Hospital and the Institute, for the support and development of those fields of cancer research and cancer treatment generally referred to as 'clinical research'.

Christmas Holiday Films and Talks on Geology

A SPECIAL Christmas holiday programme of films and talks will be held at the Geological Survey and Museum, South Kensington. The programme will include: "The Underwater Search" (December 28, film); "North Slope, Alaska", and "Fire Fight at Ahwaz" (December 29, films); "Volcanoes in Britain" (December 29, illustrated lecture); "Landforms from the Air in Canada and Iceland and New Zealand" (December 30, films); "Continents on the Move" (December 30, illustrated lecture); "The Forth Road Bridge" (December 31, film); "Geology with a Camera" (December 31, illustrated lecture); "The Story of Camp Century" and "The Glacier Climbers" (January 1, films); "The Search for Oil in Nigeria" and "Rig Move" (January 3, films); "The Forth Road Bridge" (January 4, film); "Channel Tunnel" (January 4, illustrated talk); "First Catch Your Fossil" (January 5, demonstration). Further information and tickets can be obtained from the Museum Lecturer, Geological Survey and Museum, Exhibition Road, South Kensington, London, S.W.7.

Announcements

SIR WILLIAM HILDRED, director-general of the International Air Transport Association, has been awarded the Edward Warner Award for 1965 of the Council of the International Civil Aviation Organization, for outstanding contributions to the development of international civil aviation.

ENTRIES are invited for the 1966 "Interaction of Technologies" award, made jointly by the Shell Chemical Company and the British Association for the Advancement of Science. The prize of 250 guineas, and a discretionary second prize of 100 guineas, will be awarded for the best paper submitted, before February 28, 1966, on the subject "The Problem of Technological Barriers". Further information and forms of application can be obtained from the Secretary, Shell/B.A.A.S. Award, Shell Chemical Co., Ltd., Shell Centre, Downstream Building, London, S.E.1.

A MEETING of the Burton-on-Trent Section of the Institution of the Rubber Industry will be held at Burton-on-Trent on January 31. Further information can be obtained from the Institution of the Rubber Industry, 4 Kensington Palace Gardens, London, W.8.

A COURSE of eight evening lectures on "Modern Physical Aids for the Chemist" will be held at the John Dalton College of Technology, Manchester, commencing on February 8. Further information can be obtained from Mr. P. R. Falkner, John Dalton College of Technology, Chester Street, Manchester 1.

A SEMINAR on "Relations Between the Administration and the Scientific Establishment", arranged by the Science of Science Foundation, will be held at the Ciba Foundation on January 17. Further information can be obtained from the Science of Science Foundation, c/o the Ciba Foundation, 41 Portland Place, London, W.1.

A SYMPOSIUM on "Scientific Aspects of Pest Control", arranged by the National Academy of Sciences-National Research Council and other United States Federal agencies, will be held in Washington during January 31-February 3. Further information can be obtained from the Agricultural Board, National Academy of Sciences-National Research Council, 2101 Constitution Avenue, Washington, D.C.

VISUAL OBSERVATION OF SATELLITES

ON October 20 there was an all-day discussion meeting at the Royal Society on the subject of visual observation of satellites. The meeting was organized jointly by the Royal Society and the British Astronomical Association, under the chairmanship of Prof. C. W. Allen (University of London Observatory), and was the first gathering of visual observers of satellites to be arranged by the Tracking Working Group of the British National Committee on Space Research.

The first subject discussed was the purposes of making observations. This topic was introduced by D. G. King-Hele (Royal Aircraft Establishment, Farnborough), who explained how visual observations of satellites fitted into the general pattern of satellite observations, and how they could best be used in geophysical studies. Investigations of the changes in satellite orbits have brought about great advances in two quite different branches of geophysics: the study of the Earth's gravitational field and the upper atmosphere. Visual observations will probably not be accurate enough for future investigations of the gravitational field; but they are quite accurate enough for most examinations of upper-atmosphere density and temperature, and, for the vast majority of satellites, visual observations are the only ones available. Visual observations, therefore, continue to be of great scientific importance, and since a large number of observations, ideally about 100 per week, are needed to determine accurately the orbit of a satellite, it is probably best for the limited number of visual observers to concentrate their attention on a relatively small number of satellites, particularly those with lifetimes of less than about twenty years.

Although the determination of orbits is the most important use for visual observations, nine other uses were briefly mentioned, including the improvement of predictions, observations of re-entry, the identification of satellites, observing satellites made of materials which are almost transparent to radar, observing satellites from the same launch which pass over very closely together, timing fluctuations in brightness, and various other uses.

The second subject on the programme was the techniques of observing. First there is the problem of searching for the satellite, especially when the predictions are in error, and the various stratagems for overcoming these difficulties were discussed. Next there is the question of accuracy. Since visual observations are not so accurate as those made by cameras, visual observers always have to strive for the best possible accuracy. Normally, observations are made relative to a pair of reference stars, and it was generally agreed that the best accuracy can be achieved by noting the time and position of the satellite as it passes two stars very close together, such that

the line between them lies perpendicular to the satellite's track. The accuracy to be aimed at by a visual observer, even though it will not often be achieved, is about 2 min of arc in direction and 0.1 sec in time. There was also discussion of the number of observations which an observer should make. Two observations are better than one if they are equally accurate, but there is less to be gained by making a large number of observations because of the bias error in timing. Discussion on the types of instruments used by observers showed very clearly that this is a matter of personal preference and depends more on the temperament of the observer than on objective scientific criteria. Many observers use binoculars and say that they can see twice as well with two eyes as with one, while other observers prefer to use telescopes, though their optical design and mountings are very varied.

The next topic discussed was the timing of observations, introduced by H. G. Miles (director of the Artificial Satellite Section, British Astronomical Association). Visual observers normally time their observations by starting (or stopping) a stop-watch at the time of the observation and synchronizing it with standard time signals, such as the *MST* radio signals or the Post Office speaking clock. The various possible errors arising from both stop-watches and time signals were reviewed, and the general conclusion was that the various time-standards at present used by observers are just accurate enough to introduce no significant error in visual observations, which can rarely expect to have an accuracy better than 0.1 sec. The stop-watches could introduce errors unless care was taken in rating them frequently, and running them for as short a time as possible before or after the observations.

The final subject for discussion was predictions, introduced by Mr. D. E. Smith (Radio and Space Research Station, Slough). Mr. Smith described some of the difficulties encountered by the Satellite Prediction Service at the Radio and Space Research Station and explained improvements which it was hoped to make in the near future. In the discussion which followed, many suggestions were made for particular improvements in the prediction service, and these suggestions will be taken into consideration in deciding future policy.

The meeting was attended by twenty leading British visual observers, four observers from other countries in Europe who report their observations to the British Prediction Centre, members of the kinetheodolite teams at the Royal Greenwich Observatory, Herstmonceux, and the Royal Observatory, Edinburgh, and representatives of various other organizations concerned with satellite tracking.

D. G. KING-HELE

SCIENTIFIC AND INDUSTRIAL RESEARCH IN NEW ZEALAND

IN the report of the Department of Scientific and Industrial Research, New Zealand, for 1965*, the Director-General records a staff on March 31, 1965, of 1,334. Of these, 511 were scientific officers, and the total represented an increase of 32 in the year. In all there were 562 technical officers, and of the 1,334 staff, 175 were employed in the Physics and Engineering Laboratory, 172 in the Chemistry Division, 91 in the Grassland Division and 90 in the Geological Survey. The total expenditure on these four Divisions was £343,611,

£310,086, £141,697, and £163,887, respectively, out of a total expenditure by the Department of £3,024,792. Expenditure on the Geophysics Division, with a staff of 82, was £195,950; on the Plant Diseases Division (68), £127,327; on the Soil Bureau (79), £152,516; on the Antarctic Division (23), £105,380; on the Crop Research Division (58), £107,332; and on the Information Service (47), £104,867. Expenditure on the incorporated Research Associations amounted to £230,840—the major share going to the Dairy Research Institute (£74,205) and the Wool Research Organization (£75,000).

Steady progress has been made in implementing the recommendations of the Mineral Resources Committee,

* New Zealand. Report of the Department of Scientific and Industrial Research for the year ended 31 March, 1965. Pp. 88. (H. 34.) (Wellington: Government Printer, 1965.) 3s.

and equipment is being built up and the staff strengthened. Sand deposits have been surveyed both for their economic value and also to collect information for shoreline research. The detailed survey so far has covered much of the east coast of Northland, where the modern shore and off-shore flats contain between 50 per cent and 75 per cent of lime soda feldspar. Clay deposits near Coalgate and Hororata in Canterbury, examined by the Geological Survey and Chemistry Division, contained an excellent grade of bentonite. A new series of geological maps of the main cities is being prepared and the Seismological Observatory is investigating the mechanisms of earthquakes, including theoretical research on alternative mechanisms which could cause a sudden change in the conditions of elastic equilibrium within the Earth. Earthquake occurrence has been subjected to statistical analysis, with respect both to position and to time, and members of the Applied Mathematics Division co-operating with the Geophysics Division are making a statistical analysis of the patterns of occurrence and location of earthquakes.

The Physics and Engineering Laboratory is developing a method of presenting information on the radiation output from various types of heaters for guidance in calculating the effect of the radiation on the comfort of people, by engineers and architects. The Chemistry Division has also developed automatic apparatus for separating the two types of silver and cupro-nickel coins in circulation in view of the change-over to decimal currency.

A detailed analysis of results obtained from the Bluff radar during the International Geophysical Year revealed a number of new and unsuspected features in the pattern of behaviour of the radar aurora and gave the first clues as to the over-all pattern. Increases in ground radioactivity from nuclear weapons tests continue to be studied, while the principle of the electromagnetic flowmeter has been applied to the measurement of blood flow in the heart lung machines of the cardio-thoracic surgical unit at Green Lane Hospital and also for measuring fluid flow in the artificial kidney.

Soil studies by the Grassland Division have shown that organic phosphorus may progressively accumulate under permanent pastures forming about 60 per cent of the total phosphorus in such soils. A survey of the vegetation and soils of the Tongariro National Park, initiated in 1960, is now nearing completion. A new variety of oats named 'Mapua', bred at the Cross Research Division, was selected from a 1953 cross of 'Milford', a lodging-resistant Welsh variety, and 'Onward', a plump-grained English oat. In full-scale trials since 1957-58 it was superior to all present varieties, highly resistant to lodging and of reasonably good milling quality. Since 1962 the Division has also produced three promising hybrid varieties of onion for field trials, and commercial release of New Zealand Hybrid No. 1 has already been requested. From crosses of turnips with aphid- and mosaic-resistant swedes, turnips have been selected with high field tolerance to these diseases. The work of the Plant Diseases Division on heat therapy for the control of post-harvest fruit rot has concentrated on hot-water treatment for pip fruits and peaches. With apples and pears *Botrytis* rots were not controlled at temperatures tolerable to the fruits, but the method would appear to have applications in the control of stone fruit brown rot in peaches, especially canning peaches. The new compound zeatin, extracted from the sweet corn kernels, has now been shown to be 6-(4-hydroxy-3-methylbut-2-enyl) amino-purine.

As a preliminary to detailed study of the movement of behaviour of red deer and other animals, the Animal Ecology Division is developing techniques for capture and marking. The Tobacco Research Station has undertaken a programme of breeding for resistance to *Verticillium* wilt black root rot, *Phytophthora* and mosaic virus.

Included with the Director-General's report are reports from the branches and from the incorporated research associations. The seventh annual report of the Ross Dependency Research Committee is appended. Lists of publications are included in the reports from the various branches.

FOREST HYDROLOGY

AN Advanced Science Seminar supported by the U.S. National Science Foundation was held at the Pennsylvania State University, State College, during August 29-September 10. The symposium was conducted by the School of Forestry with three other bodies: the North-eastern Forest Experimental Station, United States Forest Service; the International Association of Scientific Hydrology; and the International Union of Forest Research Organizations. Twenty-one countries were represented at the symposium by eighty-five participants, the largest single group being from the United States. Eighty-five papers and reports were delivered and the proceedings will be published during the next nine months. Sound organization and critical discussion stimulated by several invited scientists made this a successful meeting.

Many countries are concerned about the adequacy of existing and future water resources, and in most, research is being conducted into these and other problems in hydrology. Particular attention has been given to investigating the hydrological significance of different types of land use and, during the past 30-40 years, the hydrological role of forests has been studied in various parts of the world. Some well-known experiments have been conducted, particularly in the United States, Switzerland and South Africa, but investigations commenced more recently have had the benefit of modern instrumentation and better techniques from the start. The aim of these experiments is to compare the water balance of forest

catchments with adjoining catchments of a different vegetational character by showing differences in the volume and distribution of run-off. Now, energy budgets for catchments are being drawn up in addition to water balances and, with the use of neutron scatter devices for soil moisture measurement, considerable advances are being made in the study of forest hydrology. The importance of research of this type and also the timely nature of the symposium were emphasized by the severe water shortage in New York City and surrounding areas during August-September.

The symposium commenced with a review of activities in each country represented. In Israel, a country of few trees, difficulties arise from lack of water, in contrast to Taiwan with too much water and many trees. This distinction between countries where water conservation is important and those with the problem of soil conservation was most apparent. In many countries there seemed to be an unnecessary division of responsibility for hydrological research among a number of different organizations.

The second session considered forests and precipitation—the forest being regarded as a redistributor rather than a stimulator if occult precipitation was not taken into account. The problems involved in assessing precipitation over a catchment were described by Corbett (U.S.A.) using material from San Dimas Watershed. Leonard (U.S.A.) was concerned with the mathematics of inter-

ception, while Leyton, Reynolds and Thompson (Great Britain) showed that the reduction of transpiration from wetted leaves was exceeded by the accompanying increase in evaporation. Through-fall, stem-flow and interception in different stands as related to gross precipitation were given attention with the distribution of moisture in forest soils. Such matters as surface detention and drip studies, canopy cover measures and through-fall drop sizes were touched on by Zinke in a thorough review of interception investigations carried out in the United States. Snow in forests was considered in relation to transport processes and the mechanics of interception, and Martinelli (U.S.A.) gave an account of methods of increasing high altitude snow packs.

In the session on forests and soil water, the difficulties involved in defining and separating components of the hydrograph were evident in papers dealing with overland flow and sub-surface flow. Hewlett (U.S.A.) devised a response factor for classifying the hydrological performance of drainage basins in Appalachian forest areas, while Zahner (U.S.A.) dealt with estimation of moisture régimes for three forest soils, by using a balance between rainfall and potential evapotranspiration with the appropriate soil moisture release curve. Field determinations of moisture régimes beneath different vegetation types were described by Shachori (Israel), who showed that a greater reduction in moisture content was caused by maquis than by pine or pasture. There were five papers on various aspects of forest management and yield as related to soil moisture and ground water. In two of these, rise in the water table after thinning of pine and birch stands to various densities was reported, first by Holstener-Jørgensen (Denmark) for a clay area and then by Heikurainen (Finland) for peat.

Penman (Great Britain) started the session on forests and evapotranspiration by comparing theoretical evaporation from forests with observed results. Records from the Castricum lysimeters and two East African forest catchments were used to indicate how calculated evaporation values approached the difference between rainfall and run-off. Baumgartner (Germany) showed energy reasons for differing evapotranspiration rates over various types of surface, and he demonstrated that the energy available for evaporation at a grass surface was only three quarters of that for a forest. A six-year investigation of the evaporation from a Scots pine stand in south-east England was described by Rutter, and the result ($E_T = 1.20 E_0$) was accounted for in terms of the increase in evaporation of intercepted water over the reduction in transpiration. Knoerr (U.S.A.) solved the energy balance equation for a single leaf for different temperatures, humidities and stomatal resistances, and Swanson (U.S.A.) gave an example of the use of the heat-pulse velocity method of sap flow measurement in his investigation of transpiration from pine and spruce. The value of the dual approach on water balance and energy budget lines was apparent from Pereira's account of land use hydrology experiments conducted in East Africa. Various aspects of the relation between evapotranspiration and forest management (including the use of anti-transpirants) were dealt with in several papers. In one, Waggoner (U.S.A.) reported that chemical sprays used to close stomata caused a 20 per cent reduction in transpiration from single trees, but that a method of treating whole forests had to be found before a significant increase in run-off and water yield could be achieved.

In the 'Forests and Run-off' session, Lull and Sopper (U.S.A.) used records of discharge from a large number of small catchments in the north-east United States, with topographic and other characteristics of those catchments, in a series of multiple regression analyses to evolve a method of predicting various parameters of run-off. Ogiwara (Japan) was concerned with predicting flood discharges from forest catchments, and, by using a non-linear relationship which included a measure of catch-

ment wetness and rainfall, he was able to show the effect of forest cutting on floods. Differences in the volume and distribution of run-off from cleared north and south facing catchments at Coweeta were mentioned by Hibbert (U.S.A.), and later it was suggested that these differences might be linked to the small size of the cleared areas, making them unrepresentative. A second Japanese paper (Nakano) dealt with clearing forest catchments and showed that the effect of cutting in increasing flow is statistically significant at the 5 per cent level only for the first few years.

Several papers in the session on forests and soil stabilization dealt with the factors controlling erosion, such as rainfall characteristics, topography and litter cover. The quantitative measurement of erosion was discussed and the use of Middleton's dispersion ratio and Anderson's surface aggregate ratio mentioned. Margaropoulos showed how small dams and woven barriers with contour planting had been used to control erosion in Greece and the potential of high altitude sites in Austria for re-establishment of forest was reported by Aulitzky. In this paper it was reported that measurements of solar radiation had been made in excess of the solar constant by 18 per cent for periods of 10–20 min. Vegetational control of erosion in loess areas and strip mined areas of the U.S.A. was described along with New Zealand investigations of erosion.

Errors in run-off measurement, calibration methods for catchments and data processing of stream-flow were subjects discussed in the first papers in the instrumentation and techniques session. Anderson (U.S.A.) reported on new techniques in multivariate analysis applied to determining sediment yield. Wicht discussed the validity of the South African catchment experiments, but doubted that a method of analysis had been evolved which could readily show the effects of burning, cutting or the development of forest cover. Papers on digital hydrological synthesis and the use of isotopes concluded the session.

A panel discussed a variety of new instruments including several neutron scatter devices, a pressure pillow for snow measurement, snow depth markers that can be read from the air, a photo-electric device for measuring snow in the air, a snow resistograph, and an economical radiometer fitted with a mercury current integrator. A display of these and other instruments took place at the end of the symposium.

Films of a number of experimental areas in North America were shown, including one giving vivid portrayal of the fire at the San Dimas Watershed. Several experimental sites were visited, including a flood-prevention project and a waste-water renovation project. In this latter experiment, treated sewage effluent was being sprayed over croplands and over a forest area and there had been considerable increases in yield and growth, as well as appreciable ground water recharge.

From the papers and discussions it was apparent that a considerable effort had already gone into forest hydrology. In this context it is perhaps surprising that for a country with a rapidly accelerating demand for water, Britain has had such a limited research programme for evaluating relationships between the hydrology and land use of catchment areas. Although some worth-while investigations of forest hydrology have been carried out, not one has been on a catchment scale and has involved a land use change. Several experiments of this type are proposed in the programme of the Hydrological Research Unit, Natural Environment Research Council, but owing to administrative difficulties they have not yet been started. These experiments should considerably assist the understanding of the hydrological cycle in a forest environment, as they will incorporate recently developed methods of automatic data collection and analysis. It is hoped that these new methods will help in overcoming the handicap of Britain's late start in forest hydrology.

JOHN C. RODDA

RECONSTRUCTION OF PHASE OBJECTS BY HOLOGRAPHY

By PROF. D. GABOR, F.R.S.

Imperial College of Science and Technology, London

AND

PROF. G. W. STROKE, D. BRUMM, A. FUNKHOUSER and A. LABEYRIE

University of Michigan, Ann Arbor, Michigan

THE principle of wave-front-reconstruction imaging, first described by one of us in 1948 (refs. 1-3), has recently resulted in spectacular advances, notably in the form of three-dimensional 'lensless' photography and imaging, with both macroscopic and microscopic objects³⁻⁸. Excellent images have been obtained in a number of variations of the basic method, notably when the objects used were 'half-tone' intensity objects, or transparencies, rather than 'phase' objects.

'Phase' objects may be of a primary interest in a number of holographic applications, notably in microscopy, and in several other applications, where phase rather than amplitude variations in the light field may be predominantly characteristic of the physical phenomena under investigation, for example, in work with wind tunnels and in acoustical applications.

As holograms are recorded on photographic emulsions which register only intensities, not phases, one might easily believe that a hologram is not a full substitute for a real object. Indeed, the total wave-front which issues from a hologram in the reconstruction cannot be the same as the original wave-front emitted by the object, because one half of the information is missing. In order to obtain the total information one requires two holograms, which are in sine-cosine relation to one another. Two such 'complementary' or 'quadrature' holograms have been used in the 'total reconstruction microscope' by one of us⁹. Adding up the wave-fronts issuing from two such holograms, one obtains in the reconstruction the original wave-front, and nothing else, except a uniform background.

However, somewhat paradoxically, the original wave-front is also contained in the modified wave-front diffracted in the reconstruction by a single hologram. The incompleteness shows itself in the fact that this wave-front is mixed up with an additional wave, which appears to issue from a 'conjugate object'. But the two

partial wave-fronts can be separated by various methods, the simplest of which is using a skew reference beam at an angle to the plate, in the taking of the hologram. The information-theoretical paradox that an incomplete record contains the full information in a retrievable form is explained by the fact that there is a loss of one half of the definition. This, however, is as good as unnoticeable in almost all present-day applications of holography.

Consequently, since one of the two (or more) waves diffracted by the hologram in the reconstruction process contains information on both the amplitude and the phase distribution in the object, both the phase and the amplitude information may be extracted from the reconstructed wave-front, for example, by suitable 'filtering' of the aerial reconstructed images, or diffraction patterns, before the final image is recorded on a photographic film. In essence, the image-forming wave-fronts reconstructed from holograms are indistinguishable from the wave-front which would be obtained from an ideal lens or mirror looking directly at the object, when it is possible to form an image in the ordinary 'one-step' imaging, for example, in microscopy. It has therefore been clear to us for some time that we may display the phase in the holographically reconstructed images of 'phase' objects, when necessary, with the aid of any one of the several well-known methods^{10,11} (for example, phase contrast, interferometry, Foucault or Schlieren methods) used to display the phase variations in the form of amplitude variations, as used in microscopy and other phase measuring applications in optics.

Because of the great present interest in holography, and because some of our recent advances seem to indicate a good likelihood that high resolutions may indeed be attainable in microscopy at very short wave-lengths (for example, X-rays), it may be of interest to demonstrate that phase-preserving imaging and 'phase-contrast' image

Fig. 1. Modified Fourier-transform holographic image-reconstruction arrangement, permitting 'phase-contrast' detection and imaging of phase objects. The distance f_1 is equal to the distance of the object, respectively point-reference, from the hologram in the 'lensless' recording of the Fourier-transform hologram^{3,12}. 'Conventional' Fourier-transform reconstruction of the images from the Fourier-transform holograms is obtained in the absence of the 'phase filter'. (The geometrical magnification obtained in Fourier-transform holographic imaging is equal to the ratio f_2/f_1 . An additional magnification factor equal to λ_2/λ_1 is obtained, when the reconstructing wave-length λ_2 exceeds the recording wave-length λ_1 . In this work, $f_1 = 415$ mm, $f_2 = 600$ mm, $\lambda_2 = \lambda_1 = 6328$ Å.

reconstruction may indeed be readily achieved in holography, using single holograms.

As one example of the 'phase-preserving' reconstruction of the image of a phase object, we have used the arrangement shown in Fig. 1. The phase object used is shown (barely visible) in Fig. 2a, and an enlarged transmission two-beam interferogram of the object is shown in Fig. 2b.

Fig. 2a. Direct (not holographic) image of phase object used in this work, showing degree to which a 'pure' phase object was obtained by suitable bleaching of a Kodak 649F emulsion (see text, and Fig. 2b). The object is the word 'phase' and the letter 'Φ' (the word phase being 20 mm long). The slight contrast detectable is due to some slight defocusing, and some residual absorption in the plate

Fig. 2b. Two-beam single-pass interferogram (6328 Å) of the phase object used in this work. The hologram of this phase object was recorded in the 'lensless' Fourier-transform hologram recording arrangement according to ref. 12

Fig. 2c. Two-beam single-pass interferogram (6328 Å), illustrating the amount of emulsion shrinkage and corresponding phase variation achievable in a Kodak 649F emulsion with four different exposures (in ratios $\times 1$, $\times 2$, $\times 3$, $\times 4$), and suitable bleaching with Kodak chromium image intensifier, used to obtain almost pure 'phase objects', with minimum residual absorption

Fig. 3. Reconstructed image, obtained by Fourier-transform reconstruction in the arrangement of Fig. 1, without the use of any phase-contrast enhancement. (The 'lensless' Fourier-transform recording of the hologram of the object was obtained according to ref. 12.) The image shown here is characterized by an almost complete absence of any amplitude contrast in the phase-portion of the image (the various interference effects are spurious, and are caused mainly by imperfectly clean reconstructing optics). It may be noted that excellent imaging is obtained under similar conditions when the original objects are amplitude or intensity objects^{12,13}, rather than pure phase objects

The phase object was formed by photographing the word 'phase' and the letter 'Φ' on a Kodak 649F plate, and by bleaching the emulsion (using Kodak chromium intensifier as the bleacher). It is well known that photographic emulsions will shrink with the density of the exposure. (Typical emulsion shrinkage with exposure factors, 1, 2, 3, 4, is shown in Fig. 2c.) The phase object was recorded by projecting an image on to the plate deliberately slightly out of focus, in order to avoid steep gradients at the edges of the letters. (The amount of shrinkage shown in Fig. 2b was achieved in a 20-sec exposure, with a 75 W bulb, at $f/11$, in 1:1 imaging in the enlarger, and suitable bleaching.)

The hologram of the phase object was recorded in the 'lensless Fourier-transform' hologram recording arrangement, first described by one of us^{12,13}, in which the spherical waves originating from the various object points are made to interfere with a 'single' spherical reference wave, originating from a source 'point' in the mean plane next to the object. A reference wave of a radius $f_1 = 415$ mm was used in the recording. (We may note that the 'lensless' recording of the hologram permits storage of the information about the phase distribution in the object without introducing any other optical elements between the object and the emulsion, thus avoiding any extraneous scattering, which might reduce the fidelity and sensitivity of the method.)

The images reconstructed from the 'lensless Fourier-transform' hologram are shown in Figs. 3, 4 and 5. Fig. 3 shows a Fourier transform reconstruction, without filtering, obtained by simply projecting a plane monochromatic (6328 Å) wave through the hologram, and by recording one of the side-band images in the focal plane of a $f_2 = 600$ -mm lens. Unlike the reconstruction-imaging of intensity or amplitude objects, the reconstructed image of the phase object in Fig. 3 shows no amplitude contrast, because of the 'pure' phase nature of the object.

Figs. 4 and 5 show well-contrasted images of the phase object, obtained by a number of the well-known phase filtering or phase-contrast methods, in which the phase variations are made visible in the form of amplitude (that is, intensity) variations in the image.

Figs. 4a and b show the reconstructed images, obtained by a 'defocusing' phase-contrast enhancement, in a Fourier-transform reconstruction arrangement, as in the sharply focused Fig. 3, but now by recording the images together slightly ($\pm 1/4 f_2$ at $f/24$) out of focus, with respect to the in-focus image of Fig. 3.

Fig. 4c shows an in-focus image, in which the phase-contrast enhancement was obtained in the filtering arrangement shown in Fig. 1, with the help of the corner of a phase-contrast filter (also recorded photographically, and bleached, similarly to the object recording already described here).

Fig. 4a. Reconstructed image of phase object, obtained with 'phase-contrast' enhancement by defocusing (here towards the L_1 lens of Fig. 1 by $-f_2/4$, with $f_2 = 600$ mm). The length of the word in the object was 20 mm (in the image, it is 30 mm, because of the f_2/f_1 magnification (see Fig. 1))

Fig. 4b. Reconstructed image of phase object, with 'phase-contrast' enhancement, obtained by defocusing (here, out of focus, away from the lens L_1 by $+f_2/4$)

Fig. 4c. Reconstructed image of phase object, with phase-contrast enhancement obtained by using a phase-contrast filter (the corner of one of the rectangular phase strips, shown in Fig. 2c) in the arrangement of Fig. 1. (Here, the interference effects are spurious, and due to some imperfect cleanliness in the reconstruction optics)

Fig. 4d. Reconstructed image of phase object, with phase-contrast enhancement, obtained with a Foucault knife-edge used in the phase-filter plane of Fig. 1

Fig. 5. "Hologram of the hologram." Two-beam single-pass interferogram (6328 Å laser light) of the interference pattern between the reconstructed aerial image and a plane reference beam. Comparison of the image-interferogram shown here with the similarly obtained object-interferogram of Fig. 2b demonstrates that phase-distribution in the object is indeed preserved and completely reconstructed in Fourier-transform wavefront-reconstruction imaging, using a modified 'phase-contrast' enhancing arrangement, such as that illustrated in Fig. 1. (We may note that phase preservation and phase-enhancing reconstruction apply to holograms recorded at one wave-length, and reconstructed in a second wave-length, for example, when λ_1 is in the X-ray domain and λ_2 in the visible-light laser domain)

Fig. 4d shows an in-focus image, with 'phase-contrast' enhancement obtained in the filtering arrangement of Fig. 1, with the help of a Foucault knife-edge filter (at right angles to the word 'phase').

Fig. 5 shows a two-beam interferogram of the reconstructed aerial image, formed by interference of the aerial image with a plane wave (in a suitable beam-splitting arrangement): by comparing the interferogram of the phase object (Fig. 2b), the degree of phase preservation and of fidelity of 'phase-preserving' reconstruction may be readily assessed.

It is clear from a comparison of the images and interferogram of the image, of Fig. 4 and of Fig. 5, with the phase object and object-interferogram of Fig. 2, that the phase-distribution in the phase object was not only retrievably recorded in the hologram, but also that the phase in the image of the phase object can be readily displayed as an amplitude (respectively intensity) in the reconstructed image, with the aid of phase-contrast or other image-filtering methods, including interferometry of various types. We may note that there is some indication that holograms of phase objects, recorded with a $1/1$

ratio of reference/diffracted field intensity (rather than the about 5/1 used here), appear to display some noticeable 'phase-contrast' enhancement simply in the focus of the 'conventional' Fourier-transform reconstruction arrangement.

We thank R. C. Restrick for his advice. This work was supported in part by the U.S. National Science Foundation and the U.S. Office of Naval Research.

MODERN LOW-TEMPERATURE CALORIMETRY

By DR. I. M. FIRTH

Department of Physics, University of St. Andrews

PRECISION calorimetry at liquid helium temperatures began in 1929 with the development of a very sensitive phosphor bronze thermometer by Keesom and Van Den Ende¹. Since that time our knowledge of the heat capacity of solids has increased greatly; some of the discoveries in this field of measurement have been very important, such as the electronic heat capacity in metals² and the heat capacity associated with the superconductive phase transition³, both measurements agreeing remarkably well with theoretical predictions. Before 1929 the main stimulus for specific heat measurements was the known decrease in the specific heat of solids at low temperatures from the famous room temperature value of 6 cal mole⁻¹ degree⁻¹ of Dulong and Petit. In this period both theory and experiment were advanced, producing the theory of specific heats of solids by Einstein⁴, the refinement to this by Debye⁵, and the vacuum calorimeter of Nernst⁶.

Since those early days of calorimetry, experimental methods have been continually improved and now a new era of precision has been entered. This has come opportunistically, for theoreticians interested in phenomena in the neighbourhood of critical points⁷ are calling for more accurate data close to such singularities. Although modern refinements now allow an accuracy of 0.05 per cent and a temperature resolution of 10⁻⁶ °K in some cases, a great many of the older troubles of calorimetry still persist, and this remains a research topic where many experimental data are taken. Modern ways can make such recordings automatic, but calorimetry at low temperatures is still a research problem requiring all the ability of a trained physicist and the facilities of a good workshop.

Basic Measurements

The heat capacity of a specimen is defined by:

$$C(T) = \lim_{\Delta T \rightarrow 0} \frac{\Delta Q}{\Delta T}$$

and is inherently a measurement averaged over some temperature interval when made by direct methods, that is, measuring the temperature rise on adding a known quantity of heat. Only when $C(T)$ is determined indirectly, from theoretical connexions with some other parameter, is it defined at a unique temperature. At room temperature, where $C(T)$ is varying slowly, standard two-phase methods may give average values that are adequate, but at low temperatures, where the variation is rapid, it is highly important to reduce as much as possible the temperature interval over which the average is taken. The experimental problem reduces, therefore, to isolating the specimen from its surroundings to a high degree and measuring the heat input ΔQ and the temperature rise ΔT as accurately as possible.

At low temperatures the most convenient source of ΔQ is Joule heating so that ΔQ is evaluated from measurements of electrical power and time. Where heat is applied intermittently in pulses the total heat input is correlated with the temperature difference between the initial and final states of equilibrium. The other method of applying heat in practical calorimetry is to do so continuously and requires electrical power to be compared with the rate of change of temperature. There are important differences between these two techniques which dictate their suitability to modern methods and methods of automatic recording.

As well as controlled Joule heating there will be an extraneous heat input over which the experimenter has limited control. This unwanted heat input can be said to occur through heat conduction and heat transfer by radiation. By the first, heat leaks to the calorimeter through its suspension threads and through the residual gas in the vacuum chamber surrounding the calorimeter, but both can be kept very small. Radiation of heat to the calorimeter occurs through emission and absorption of light and other electromagnetic radiation, and acoustical energy transfer. Often the latter two processes are the more important and can be minimized by screening apparatus from high-frequency radio sources—television transmissions often contribute to this factor through pick-up—and by isolating the whole calorimeter apparatus from vibrations.

In sensitive specific heat measurements the heat leak must be measured and corrected for, or kept low and sensibly constant so that it does not affect measurements. In the heat-pulse method a correction for the extraneous heat input is found for each pulse. Individual corrections of this type would be indispensable where the heat leak is large and varying with time over the temperature range of interest, but at low temperatures the heat leak can be kept small and constant for fairly long times. The method is therefore more powerful than is required here and has, in addition, certain shortcomings. First, as the heat pulse is generally of short duration, the electrical measurement of ΔQ may be difficult to make accurately, for currents of a few μ amp and voltages of a few μ V have to be measured. Secondly, as there is inevitably some thermal resistance between the calorimeter and the sample, and as the thermal conductivity of the sample may not be high, the recorded temperature, that is, of the calorimeter, is always somewhat higher than the mean temperature of the specimen. This temperature difference can become quite large during a heating pulse and gives rise to the so-called 'over-heating' effect⁸ (see Fig. 1), and the time to re-establish equilibrium may be long.

Corrections for over-heating can be made accurately by extrapolating the linear portions of the temperature

variation curve to the middle of the heating pulse and equating areas x , y to z . This method, therefore, requires a continuous recording to be made of temperature against time on both sides of the pulse. Corrections and extrapolations are then made from geometrical manipulations of this record, and the number of points so treated is limited by the time it takes the calorimeter temperature to reach equilibrium and by the patience of the observer. A maximum of data per degree Kelvin may be twenty.

There is also experimental evidence for not using this technique: Shiffman⁹ has observed that in the same temperature range the calculated specific heat may vary from pulse to pulse indicating that electrical transients lead to discrepancies between the real heat input and that measured.

Automatic schemes¹⁰ have been reported which use the heat-pulse technique. Temperature readings are taken at specified time intervals before and after the pulse. In manipulating the data so recorded, a computer can be programmed to make the appropriate extrapolations if the linear portions only of the drift curves are used. Important data may have to be neglected intentionally, and from the discussion of over-heating by Parkinson and Quarrington, it is apparent that results of great accuracy may not be obtained.

The continuous heating method, on the other hand, requires accurate instantaneous measurement of temperature and of input of power at specified times. Because heat is applied continuously, a state of dynamic thermal equilibrium is attained even in samples of low conductivity. Where the highest temperature resolution is required the heater power can be reduced accordingly, but the reduction can only be made to the level of the extraneous heat input so that again, to obtain high resolution, the experimenter must emphasize high thermal isolation in his design.

This method has been discussed in detail by Cochran¹¹. During continuous heating the electronic bridge used to measure temperature is repeatedly unbalanced by very small steps in a sense that the bridge returns to balance as the heating progresses. The time taken between successive balances is measured by electronic counters and, as the temperature jump between balances is small, the heat capacity is related linearly to the power input and the time interval. There is little doubt about the meaning of recordings here, as there may be in the pulse method, and automatic recording schemes can be used with ease, for data can be presented in digital form. As many readings can be taken as the warning rate will allow, and about a hundred readings can be made per degree Kelvin. Although the accuracy of each reading is high in itself, the large amount of data that can be recorded in this fashion makes it possible to achieve higher accuracy by statistical methods of analysis.

The method can be used to evaluate the extraneous heat input to the calorimeter, heating is stopped and the temperature drift caused by the various heat leaks is observed. A check on the heat leak is obtained also by

repeating heat capacity measurements with varying electrical heat inputs knowing that the heat capacity remains constant, so obtaining the heat leak from a difference equation. Careful attention to technique and design has enabled heat leaks of 1–10 ergs per sec, a temperature resolution of 10^{-6} °K and an accuracy in specific heat of 0.05 per cent to be obtained.

Thermometry

Temperature in the range of 0.2–5 °K is generally measured by means of a secondary thermometer. Commercial carbon radio resistors, especially made to be temperature insensitive at room temperature, were found some years ago to be most usefully sensitive at low temperatures¹². For calorimetry they have the desirable properties of high sensitivity, low heat capacity, low sensitivity to measuring current and to magnetic fields, and low cost. Carbon resistors are affected, however, by cycling to room temperature and their resistance-temperature response is reproducible to about a millidegree. More undesirable than this is, in principle, the fact that full equilibrium of the response is not attained for some 8 days when the resistors are held at low temperature, implying, in general, some change in characteristic during any experiment. It is most likely that, now they have been made available commercially, doped germanium thermometers will supplant carbon resistors as the most used secondary thermometer, since they exhibit little change of response in cycling to room temperature and much more rapidly attain equilibrium.

The most important aspect of calorimetry is the calibration of the thermometer because the accuracy of the whole experiment depends largely on this. As much experimental time is spent in comparing the resistance of the carbon resistance thermometer to the temperature of the liquid helium bath, it is important that an exact analytical description is obtained. There have been many suggestions how improvements can be made to the approximate formula suggested by Clement and Quinell¹²:

$$\left(\frac{\log R}{T}\right)^{\frac{1}{2}} = a + b \log R$$

where R is the measured resistance, T is the absolute temperature, and a and b are constant parameters. (Once the constant parameters have been evaluated for a resistor, this formula is used with a correction graph showing the deviation of the actual response in later experiments from the response defined by the particular a and b .) The most notable of these improvements is that by Moody and Rhodes¹³, who introduced an expression involving a large number of adjustable parameters in the form:

$$\frac{1}{T} = \sum_n a_n (\log R)^n$$

where $n = 0, 1, 2, \dots$. This formula permits easy recalculation of all the parameters to high accuracy after each calibration and removes the necessity for using inconvenient correction graphs. An exact analytical description of the temperature response facilitates subsequent conversion of resistance to temperature in calculations to determine the specific heat and indicates a great advance in the manipulation of the calibration procedure.

An important part of the calibration procedure is that a computer is programmed to perform the calculations. The root-mean-square deviation is calculated and calibration points that are above a pre-set value, for a given value of n , are rejected: the parameters are then recalculated until the allowed deviation is not exceeded. This method is compatible and can be used to advantage with the scheme already outlined here where the resistance of the thermometer is recorded automatically against the bath temperature.

For highest precision, carbon resistance thermometers must be used in a suitable bridge circuit where the power dissipation is kept low, that is, less than 10^{-8} W. Prior

Fig. 1. Over-heating of calorimeter during an input pulse of heat.
—, Calorimeter temperature, ----, sample temperature

Fig. 2. A.C. bridge to determine the resistance of the temperature sensitive resistor using a lock-in amplifier

to the carbon-resistance thermometer, resistance thermometry had utilized a variety of resistance-measuring techniques among which were the potentiometer method, the Thomson double-bridge method and the Wheatstone bridge method. All are capable of high resolution but require to be adjusted by hand, involving up to four operations for the measurement of resistance between branch points and are not suited to any experiment that requires an instantaneous indication of temperature.

With the carbon resistance thermometer came the necessary advance in accurate instantaneous resistance measurement¹⁴. A simple Wheatstone bridge is most generally used with a high-gain, lock-in amplifier as detector. Such a bridge is shown in Fig. 2 and is similar to that used by Buckingham and Fairbank¹⁵ in their famous experiment on the specific heat of liquid helium at the superfluid transition temperature. Bridges of this type can detect changes of 10^{-7} °K, that is 0.02 ohm in 50 kohms where the power dissipated in the carbon resistor is about 10^{-10} W. It is this type of temperature-measuring system that was referred to earlier.

Automatic Recording and Calculation

There can be now few workers who manually calculate specific heats from experimental data, for the repetitive calculations involved can be better done, in less time, by computer. With a well-designed method of undertaking the experiment, data can be recorded automatically on to any of the many media used for feeding data to digital computers, paper tape, magnetic tape or punched cards, so reducing the overall time required to perform the calculations and, at the same time, reducing the errors in recording large amounts of data—the human operator with a desk calculator is only about 95 per cent accurate.

From what has been said already, it seems more meaningful to use the continuous heating technique with auto-

matic recording equipment. In this technique the power input can be monitored by repeatedly recording current and voltage to the calorimeter heater; the time between known small temperature jumps is easily available from an electronic timer as is the temperature jump which is in the form of a digital setting of a calibrated resistance box. The extraneous heat input, manifested by a temperature drift, can be recorded in a similar fashion as can the thermometer calibration information, except here the bath temperature would be recorded against a definite balance point of the Wheatstone bridge.

Data recorded in this way would be processed by a computer when programmed appropriately. The programme would be in two parts: first, the thermometer calibration data would be converted into analytical form; secondly, from measurements of ΔQ and ΔT and of the extraneous heat input and from information about the heat capacity of the empty calorimeter and mass of the sample, the specific heat of the sample would be calculated.

It should be emphasized that to take full advantage of this modern, logical modification to calorimetric practice both technique and data recording procedures have to be carefully considered. Precautions must be taken to ensure that necessary information is not discarded in the process of recording and that sufficient checks are included in the whole process, from apparatus to final results, so that meaningful results are obtained with the required overall accuracy.

Much has been accomplished since the time of Nernst in this field of research to ease the burden of the experimentalist. Automatic methods will not reduce the time necessary to take experimental data, however, but final results, which before might have taken between 30 and 40 h by manual calculation, can be obtained in 30 min of computer time. The research worker must not be entranced, however, by these advances and must be continuously vigilant of his techniques in order to maintain the older standards.

PROGRESS IN THE PLANKTONIC FORAMINIFERAL BIOSTRATIGRAPHY OF THE NEOGENE

By DR. F. T. BANNER and DR. W. H. BLOW

Exploration and Production Research Division, British Petroleum Co., Ltd., Chertsey Road, Sunbury-on-Thames

CURRENT research into the value of planktonic foraminifera (particularly the Globigerinacea) as biostratigraphical indexes for the Neogene has now reached the stage of refinement wherein 23 zones may be recognized within the interval from the Miocene to the Recent. These zones may be identified in sediments of the circum-equatorial areas of the world, and many have also been directly recognized by us in temperate areas. The zones have been established by the examination of the succession of fossil faunas in Venezuela, Colombia,

Ecuador, Trinidad, Barbados, Carriacou, Jamaica, U.S. Gulf Coast, Fiji, Saipan, Guam, Christmas Island, Papua, New Guinea, West Irian, Java, Sumatra, New Zealand, Australia (Victoria), Japan (Shikoku), Tanganyika, Iran, Greece, Sicily, Italy, Libya, south-west France, Austria, the Atlantic and Pacific oceans (deep-sea cores), and other areas. The sequence of zones distinguished is as follows, from top to base stratigraphically:

Zone N. 23: *Globigerina calida*—*Sphaeroidinella dehiscens excavata* n. sub-sp. assemblage-zone; characterized by

the assemblage of *G. calida forma typica* Parker, *S. dehiscens excavata* (n. sub-sp. diagnosed by its deeply excavated sutures exposing the inner whorls¹), *Globigerina megastoma*, *Hastigerinella digitata*.

Zone N. 22: *Globorotalia* (*G.*) *truncatulinoides* partial-range-zone; defined by that part of the range of the nominate taxon prior to the first appearance of the Zone N. 23 assemblage.

Zone N. 21: *Globorotalia* (*G.*) *tosaensis* consecutive-range-zone; defined by that part of the range of the nominate taxon prior to the first appearance of its immediate descendant, *G. (G.) truncatulinoides*, the two taxa being phylogenetically consecutive.

Zone N. 20: *Globorotalia* (*G.*) *multicamerata*—*Pulleniatina obliquiloculata* (s.s.) partial-range-zone; defined by that part of the concurrence of the ranges of the two nominate taxa subsequent to the extinction of *Globoquadrina altispira* (which occurs within the range of *P. obliquiloculata* s.s.) and prior to the advent of *Globorotalia* (*G.*) *tosaensis* (which, in turn, occurs at a horizon virtually the same as that of the extinction of *G. (G.) multicamerata*²).

Zone N. 19: *Sphaeroidinella dehiscens* (s.s.)/*Globoquadrina altispira* (s.s.) concurrent-range-zone; defined by the interval of concurrence of the ranges of the two nominate taxa.

Zone N. 18: *Globorotalia* (*G.*) *tumida tumida*—*Sphaeroidinellopsis subdehiscens* partial-range-zone; defined by that part of the concurrence of the ranges of the nominate taxa which occurs before the first evolutionary appearance of *Sphaeroidinella dehiscens* (s.s.) from its immediate ancestor, *Sphaeroidinellopsis subdehiscens* (s.l.).

Zone N. 17: *Globorotalia* (*G.*) *tumida plesiotumida* consecutive-range-zone; defined by that part of the range of the nominate taxon which occurs prior to the first appearance of its immediate descendant, *G. (G.) tumida* (s.s.), the two taxa being consecutive in appearance, phylogenetically³.

Zone N. 16: *Globorotalia* (*Turborotalia*) *acostaensis* (s.s.)—*G. (G.) merotumida* partial-range-zone; defined by that part of the range of *G. (T.) acostaensis* (s.s.) which occurs before *G. (G.) merotumida* gives rise to its immediate descendant, *G. (G.) tumida plesiotumida*³.

Zone N. 15: *Globorotalia* (*Turborotalia*) *continuosa* partial-range-zone; defined as that part of the range of the nominate taxon which occurs after the extinction of *G. (T.) siakensis* and before the first evolutionary appearance of *G. (G.) acostaensis* from its immediate ancestor, *G. (T.) continuosa*.

Zone N. 14: *Globigerina nepenthes*/*Globorotalia* (*Turborotalia*) *siakensis* concurrent-range-zone; defined by the concurrence of the two nominate taxa.

Zone N. 13: *Sphaeroidinellopsis subdehiscens*—*Globigerina* n.sp.aff. *nepenthes* partial-range-zone; defined by that part of the range of *S. subdehiscens* (s.s.) which occurs before the evolutionary first appearance of *Globigerina nepenthes* from its immediate ancestor, *G.n.sp.aff. nepenthes*.

Zone N. 12: *Globorotalia* (*G.*) *fohsi* partial-range-zone; defined by that part of the range of the nominate taxon as redefined and restricted⁴, which occurs before the first evolutionary appearance of *Sphaeroidinellopsis subdehiscens* from its immediate ancestor, *S. seminulina* (s.s.).

Zone N. 11: *Globorotalia* (*G.*) *praefohsi* (n.sp., MS⁴), consecutive-range-zone; defined by that part of the range of the nominate taxon which occurs before the first evolutionary appearance of its immediate descendant, *G. (G.) fohsi*, the two taxa being phylogenetically consecutive.

Zone N. 10: *Globorotalia* (*Turborotalia*) *peripheroacuta* (n.sp., MS⁴) consecutive-range-zone; defined by that part of the range of the nominate taxon which occurs before the first evolutionary appearance of its immediate descendant, *G. (G.) praefohsi*, the two taxa being phylogenetically consecutive.

Zone N. 9: *Orbulina suturalis*—*Globorotalia* (*Turborotalia*) *peripheroronda* (n.sp., MS⁴) partial-range-zone; defined by that part of the range of *O. suturalis* which occurs before *G. (T.) peripheroronda* gives rise to its immediate evolutionary descendant, *G. (T.) peripheroacuta*, the two latter taxa being phylogenetically consecutive.

Zone N. 8: *Globigerinoides sicanus*⁵—*Globigerinatella insueta* partial-range-zone; defined by that part of the range of *Globigerinatella insueta* which is concurrent with the earliest part of the range of *Globigerinoides sicanus*, but which occurs before the first evolutionary appearance of *Orbulina suturalis*⁶.

Zone N. 7: *Globigerinatella insueta*—*Globigerinoides quadrilobatus trilobus* partial-range-zone; defined by that part of the range of *Globigerinatella insueta* which occurs after the extinction of *Globigerinita dissimilis* (s.l.) but which also occurs before the first evolutionary appearance of *Globigerinoides sicanus* from its immediate ancestor, *G. quadrilobatus trilobus*, the latter two taxa being phylogenetically consecutive.

Zone N. 6: *Globigerinatella insueta*/*Globigerinita dissimilis* (s.l.) concurrent-range-zone; defined by the concurrence of the two nominate taxa.

Zone N. 5: *Globoquadrina dehiscens praedeheiscens*—*G. dehiscens dehiscens* partial-range-zone; defined by that part of the interval during which the evolution from *G. dehiscens praedeheiscens* to *G. dehiscens* (s.s.) occurs and during which morphologically intermediate specimens are frequent, which is above the horizon of extinction of *Globorotalia* (*Turborotalia*) *kugleri* and yet which is below the horizon of first appearance of *Globigerinatella insueta*.

Zone N. 4: *Globorotalia* (*Turborotalia*) *kugleri* total-range-zone; defined by the total range of the nominate taxon.

Zone N. 3: *Globigerina angulisuturalis* partial-range-zone; defined by that part of the range of the nominate taxon which occurs above the horizon of extinction of *Globorotalia* (*T.*) *opima* (s.s.)⁷ and below the horizon of first appearance of *G. (T.) kugleri*.

Zone N. 2: *Globigerina angulisuturalis*/*Globorotalia* (*Turborotalia*) *opima* (s.s.) concurrent-range-zone; defined by the concurrence of the nominate taxa.

Zone N. 1 (= P.20): *Globigerina ampliapertura* partial-range-zone; defined by that part of the range of *G. ampliapertura* (s.s.) which occurs after the horizon of extinction of the last-surviving species of *Pseudohastigerina* (e.g., *P. naguawichiensis*) yet which occurs before the first appearance of *G. angulisuturalis*.

Careful re-assessment of the zones proposed for parts of the Neogene by Bolli⁸, Blow⁹, Blow and Banner¹⁰ and others¹¹⁻¹³ has shown that, while much of the zonation deduced from Caribbean (Trinidad, Venezuela) and East African (Tanzania) successions retains considerable validity when applied on a world-wide basis, modifications have proved necessary, as already indicated. For example, the '*Globigerina ampliapertura* zone' and the '*Globorotalia opima opima* zone', as previously understood⁸, had to be redefined following observation of the stratigraphic overlap of these two nominate taxa. The zones already proposed not only can be recognized directly in tropical and sub-tropical assemblages, but many sequences from the complete succession have been observed to occur in temperate latitudes. The complete documentation for the zonal sequence will be published elsewhere, when the succession of planktonic foraminiferal faunas will be described in relation to these zones, to the local stratigraphic succession in each area examined, to the biostratigraphical evidence of the associated fossils, and to geographic provincialization of the fossil faunas. The principal geostatigraphic results may be briefly summarized here.

The Oligocene has been found to contain two planktonic foraminiferal zones (termed P.18 and P.19)¹⁴; Zone N. 1 appears to straddle the boundary between the Late Oligocene and the Early Miocene, and has thus been

equated, in the above scheme, to Zone P. 20, the last zone of the Palaeogene. Zone N. 4 occurs at or near the base of the holostratotype Aquitanian stage¹⁵, older Neogene zones being present in parastratotypes of this stage (which may have to be accommodated by the Bormidian¹⁶ stage). The holostratotype Langhian¹⁷ contains Zones N.8, N.9 and N.10 (at least), and the holostratotype Tortonian contains the uppermost part of Zone N.15, all of Zone N.16 and the lower part of Zone N.17. Stratigraphically intermediate zones may be represented in the Serravallian¹⁸; but this has not yet proved directly determinable, as the stage lacks a precisely designated stratotype. The higher levels of the Vindobonian¹⁹, as exemplified by the 'Bulimina-zone' (or *Bolivina dilatata* zone) of the Badener series²⁰ at Nussdorf²¹, include Zone N.15 and/or Zone N.16. Zone N.17 is present in the Messinian²², as stratotypified²³. Zone N.19 occurs in the lower Pliocene (Zanclean²⁴ and Piacenzian²⁵), whilst Zone N.18 appears to straddle the Pliocene/Miocene boundary. The 'Sphaeroidinella-datum' of Bandy¹³ does not correspond precisely to the base of our Zone N.19, for that 'datum' was based upon an incomplete succession in the Philippines^{26,27}, where *Sphaeroidinella dehiscentis* appeared abruptly immediately above a hiatus marking the Pleistocene/Miocene disconformity. *Globorotalia* (*G.*) *truncatulinoides* (s.s.), which also first appeared at the so-called 'Sphaeroidinella-datum' in the Philippines, marks the base of Zone N.22, the zone which we have recognized to occur in the lower part of the stratotype Calabrian of Santa Maria di Catanzaro²⁸, the agreed earliest Quaternary²⁹.

In the Far East, it appears that the top of the 'Te-stage'³⁰ occurs within Zone N.9, and that the top of the 'Tf-stage' occurs either within Zone N.14 or near the base of Zone N.15. The base of the 'Tf₃' division³¹ has been estimated to occur within Zone N.12–N.13.

It must be noted that a re-investigation of the so-called 'Globorotalia fohsi lineage'⁸ has been completed, resulting in a complete taxonomic, nomenclatural and biostratigraphical revision⁴ of the indexes and of the zones as previously understood⁹ and described from Trinidad³ and Venezuela⁹ in particular. Comparison with other areas has shown the presence of a diastem between the Lengua and Cipero formations in Trinidad³, Zone N.13 being eliminated there by the hiatus; this has necessitated revision of the so-called 'Globorotalia mayeri zone'⁸. Very rich sequences of planktonic foraminiferal faunas from Jamaica have shown that the Bowden Shell Bed, long famed for its rich mollusc assemblages³², lies within Zone N.19. The planktonic foraminiferal assemblage of Zone N.19 has independently been recognized to occur in at least three deep-sea cores from c. 100 cm below sea-floor in the Pacific Ocean³³.

We thank Dr. F. E. Eames, chief palaeontologist, British Petroleum Co., Ltd., for his advice, and all our

colleagues for their advice, criticisms, sample donations and geological information.

2-TRIFLUOROMETHYLBENZIMIDAZOLES: A NEW CLASS OF HERBICIDAL COMPOUNDS

By DR. D. E. BURTON, DR. A. J. LAMBIE, J. C. L. LUDGATE, DR. G. T. NEWBOLD, DR. A. PERCIVAL and D. T. SAGGERS

Chesterford Park Research Station, Fisons Pest Control, Ltd., Saffron Walden, Essex

THE synthesis of 2-trifluoromethylbenzimidazole was published in 1953¹ and since then a score of benzene-ring-substituted derivatives have been described in the literature, mainly emanating from the Birmingham School of Organic Chemistry^{2–8}. Antibacterial⁸ and antiviral⁹ properties of some of these compounds have been described.

During the past five years, workers in our laboratory have been interested in the preparation of various heterocycles derived from *o*-phenylenediamines¹⁰, for example, benzotriazoles¹¹, quinoxalines¹² and benzimidazoles¹³, and particularly, but not exclusively, in those bearing halogen substituents in the benzenoid ring. This led us, in early 1962, to embark on the systematic study of the synthesis

and biological behaviour of 2-trifluoromethylbenzimidazoles, of which a large number have been made having a free hydrogen on the 1-position, most being hitherto undescribed in the literature. Early in this investigation it became evident that the group possessed interesting herbicidal activities, though these appeared to be associated with high mammalian toxicity. Further synthesis and biological examination, however, showed that these two properties were not inseparably associated and that an acceptably safe and yet active herbicide could be obtained.

Some members of the 2-trifluoromethylbenzimidazole series show interesting and possibly important insecticidal activity principally by ingestion, but their foliar-protectant interest is limited by phytotoxicity. A high level of molluscicidal activity is also shown by certain members, for example, 4-bromo-5,6,7-trichloro-2-trifluoromethylbenzimidazole with an LC_{50} against *Australorbis glabratus* of 0.1 p.p.m.

Aspects of the chemistry of 2-trifluoromethylbenzimidazoles will be published elsewhere; their preparation was effected by reaction of *o*-phenylenediamine with trifluoroacetic acid or by direct substitution of 2-trifluoromethylbenzimidazoles. The resulting compounds are acidic with the pK_a decreased by about 4–4.5 units from that of the corresponding benzimidazoles with hydrogen in the 2-position. pK_a 's of 2-trifluoromethylbenzimidazoles vary from 8.79 in the case of the unsubstituted compound to the highest acidity in our series, 2.96, for 4,7-dichloro-5,6-dinitro-2-trifluoromethylbenzimidazole.

Evaluation of herbicidal activity was made on two stages of plant growth. In the first test (post-emergent) the toxicity to the aerial portions was assessed by applying a solution of the compounds in aqueous acetone to the foliage of a selection of young crop plants.

In the post-emergent test the typical symptoms induced by the active members of the series were rapid loss of turgidity, necrosis and death of plant within about four days. In the most resistant species the necrotic areas were confined to the areas of spray drop retention.

There was no evidence of significant translocation and the rate of necrosis appeared to be independent of light.

Acute oral toxicity values in the female rat were obtained by standard techniques by our colleague, Mr. D. M. Sanderson. The principal toxic effects were dyspnoea, weakness, occasionally salivation and death in an extended position with immediate rigor mortis. The latter observation is similar to that made on other compounds causing uncoupling of oxidative phosphorylation¹⁴. This possibility has been investigated by our colleagues, Dr. O. T. G. Jones and Mr. W. A. Watson, and it has been confirmed that the most biologically active 2-trifluoromethylbenzimidazoles are powerful uncouplers of oxidative phosphorylation¹⁵.

Examples of this class of compounds are the 5-substituted-2-trifluoromethylbenzimidazoles (Table 1). These derivatives show the typical herbicidal spectra associated with this series. The pK_a of the benzimidazole seems to be an important factor influencing good herbicidal activity. Compounds with electron attracting groups in the 5-position would appear to be more active than those with electron-donating groups at this position. The activity of the parent 2-trifluoromethylbenzimidazole is significantly enhanced by 5-halo-substitution in the sequence 5-I = 5-Br > 5-Cl > 5-F (Table 1). The other derivatives containing an electron-withdrawing group, for example, 5-cyano-, 5-nitro- and 5-trifluoromethyl-, have the same overall activity as the 5-iodo-2-trifluoromethylbenzimidazole. An electron-donating group at the 5-position, for example, 5-methyl-, 5-methoxy- or 5-amino-, has little effect on the herbicidal activity of the parent compound. A marked feature of this series is the variation in species selectivity with slight modification to the structure. This can be seen in the halo- series where selectivity in favour of peas is increased four-fold in proceeding from the 5-fluoro to the 5-iodo derivatives, while the reverse occurs in the case of barley. In general the mammalian toxicity tends to follow the herbicidal trend with the exception that the 5-iodo and 5-bromo-compounds, while having greater herbicidal activity than

* The species used were peas, *Pisum sativum*; mustard, *Sinapis alba*; linseed, *Linum usitatissimum*; beet, *Beta vulgaris* (var. Sharpe's Klein E); buckwheat, *Fagopyrum esculentum*; and barley, *Hordeum vulgare* (var. Proctor). The chemical was applied by means of twin air-atomizing gravity-fed spray guns (Bullows type L 500) mounted over a turntable, the speed of rotation of which was adjusted so that the plants received a volume equivalent to 80 gallons/acre. The initial application rate was 10 lb./acre which was halved on successive retests until no significant response was observed. The measurement of activity took the form of a visual assessment seven days after chemical application. The species were scored individually on a 0–100 rating where 0 = no effect and 100 = complete kill. In certain of the tables presented the arithmetic mean of the individual scores is given as being the most representative value for overall herbicidal activity. The LD_{50} levels were obtained by plotting the dosage/score curve on log-probit analysis paper and obtained by eye from a line of best fit.

All tests described here were carried out in controlled environment rooms at a temperature of 22° C with 14 h of artificial illumination (at an intensity of 0.000 ft.-candles), using daylight fluorescent lighting. The soil used was John Innes No. 1 potting compost and the plants were grown in small anodized aluminium pans ('Ovenex' were 7.5 × 3.75 × 2 in.) drilled in the base for drainage. Plants were tap watered throughout the period of the experiment.

† Determined spectrophotometrically in water at 20° by Messrs. D. Hughes, W. Mason and Miss P. M. Palmer.

‡ Zwitterion.

§ Dihydrochloride.

the 5-chloro-2-trifluoromethylbenzimidazole, have lower mammalian toxicity.

The effect of the different substitution patterns on the herbicidal activity is shown by the chloro-substituted derivatives (Table 2). Maximum overall activity is shown by the 4,5,6-trichloro-2-trifluoromethylbenzimidazole (pK_a 6.18). Of particular interest is the considerable increase in mammalian toxicity and decrease in herbicidal activity of the 4,5,6,7-tetrachloro- derivative as compared with the trichloro- derivatives. One of the more promising members of the series so far is 4,5-dichloro-2-trifluoromethylbenzimidazole, *NC* 3363, for which the common name chlorflurazole is proposed, which shows a high contact toxicity to many broad-leaf species at a rate which is safe to cereals, combined with a fairly low mammalian toxicity. Further tests with this compound have confirmed that it is active against a range of cereal weeds, such as chickweed, spurry, mayweed and fat-hen, and that it can be markedly synergized by addition of certain herbicides of the phenoxyacetic range. The field performance of such mixtures will be reported elsewhere by our colleague Dr. R. K. Pfeiffer¹⁶.

In comparison the 4,6-dichloro-2-trifluoromethylbenzimidazole shows a relatively high toxicity to barley.

In the mono- and di-substituted halogen series the bromo- derivatives were superior in herbicidal activity and less toxic to mammals than the chloro- compounds; this advantage is lost in higher substitution.

Introduction of a nitro-group into the substitution pattern produces the characteristic selectivity shown by the other members of the series (Table 3). In the nitro-halogen series the 4,6-substitution pattern gives compounds of good herbicidal activity. The 6-nitro-4-halo derivatives produce compounds with an acceptable safety factor to peas and barley without adversely influencing activity on the other broad-leaved weed species or mammalian toxicity. However, 4-nitro-6-halo derivatives have higher mammalian toxicities without improved selectivity. The dinitro- derivatives were not as active as their dichloro- analogues. The nitro-dichloro-substituted compounds had reduced activity compared with the corresponding disubstituted chloro-compounds. The nitro-trichloro- and dinitro-dichloro- derivatives were of only slight interest herbicidally, although they were of

considerably lower mammalian toxicity than the 4,5,6,7-tetrachloro-compound.

The tetra-halogen substituted 2-trifluoromethylbenzimidazoles are compounds of high mammalian toxicity. Replacement of a chloro group by a methyl, sulphonamido, piperidino or morpholino group did in fact lower mammalian toxicity but the herbicidal activity was correspondingly decreased.

The pK_a values of these compounds are obviously a measure of one of the significant factors effecting herbicidal activity and we found that most of the compounds having good herbicidal activity have a pK_a in the range 5–8. The 5-*t*-butyl compound is an exception; the correlation between pK_a and biological activity will be discussed in a separate paper.

Substitution at the 1-position with alkyl or aralkyl groups gives compounds of considerably less herbicidal activity than the derivatives having a free hydrogen on the nitrogen atom in the 1-position.

By comparison with the post-emergent response, the pre-emergent activity of the 2-trifluoromethylbenzimidazoles, although not insignificant, is of less interest.

However, certain members of the series have shown selective properties, particularly in cotton, which is at present under further investigation. The symptoms of toxicity in the sensitive species are marked germination reduction with chlorosis followed by necrosis and death.

ACTIVITY OF 2-TRIFLUOROMETHYLBENZIMIDAZOLES AS UNCOUPLERS OF OXIDATIVE PHOSPHORYLATION

By DR. O. T. G. JONES and W. A. WATSON

Chesterford Park Research Station, Fisons Pest Control, Ltd., Saffron Walden, Essex

THE herbicidal and insecticidal properties of a series of substituted benzimidazoles have been described by Burton *et al.*¹ These compounds are derivatives of 2-trifluoromethylbenzimidazole:

and are related in structure to 4,5,6,7-tetrachlorobenzimidazole, a compound investigated at these laboratories and known to possess activity as an uncoupler of oxidative phosphorylation². Preliminary observations suggested that the 2-trifluoromethylbenzimidazoles also acted as uncouplers and the experiments described in this communication confirm this activity.

Rat liver mitochondria were prepared in 0.25 M sucrose by standard methods³ so that 2 ml. of mitochondrial suspension was obtained from each gram of liver. For oxidative-phosphorylation measurements, incubations were carried out for 20–30 min at 30°; the incubation mixture contained, in a final volume of 3 ml., glycylglycine (50 μ moles), KCl (375 μ moles), $MgCl_2$ (42 μ moles), glucose (180 μ moles), NaF (45 μ moles), AMP (6 μ moles), ATP (6 μ moles), cytochrome *C* (0.036 μ mole), yeast hexokinase (200 *KM* units), potassium phosphate, pH 7.4 (46.2 μ moles), substrate 30 μ moles and about 1 mg mitochondrial nitrogen. Uptake of oxygen was measured using the Warburg apparatus, uptake of phosphate by the method of Fiske and Subbarow⁴ after the addition of perchloric acid (0.5 ml. of 50 per cent v/v) to end the incubation.

ATPase activity was determined by the method of Lardy, Connelly and Johnson⁵.

In Table 1 the uncoupling activity of some of the 2-trifluoromethylbenzimidazoles is compared with that of tetrachlorobenzimidazole and 2,4-dinitrophenol. It can

be seen that the tetrachloro-2-trifluoromethylbenzimidazole is active at much lower concentrations than dinitrophenol; 50 per cent uncoupling being achieved at 8.2×10^{-8} M. Similar results were obtained with other 2-trifluoromethylbenzimidazoles with succinate, glutamate, pyruvate and β -OH butyrate as substrates.

The activity of 2-trifluoromethylbenzimidazoles in stimulating the ATPase of rat liver mitochondria is shown in Table 2. Tetrachloro-2-trifluoromethylbenzimidazole increased ATPase activity at concentrations much lower than those required for 2,4-dinitrophenol to be effective. As would be expected from such uncoupling agents, the 2-trifluoromethylbenzimidazoles stimulated respiration of mitochondria in the absence of a phosphate acceptor. Similar results have been obtained for many 2-trifluoromethylbenzimidazoles.

The 2-trifluoromethylbenzimidazoles behave as weak acids¹ and thus resemble the well-known uncouplers, the

Table 1. ACTIVITY OF SOME 2-TRIFLUOROMETHYLBENZIMIDAZOLES IN UNCOUPLING OXIDATIVE PHOSPHORYLATION COMPARED WITH COMPOUNDS OF KNOWN ACTIVITY

Compound	Conc. required for 50% uncoupling of oxidative phosphorylation (M)
2-Trifluoromethylbenzimidazole	Inactive up to 4.2×10^{-4}

2	"	3×10^{-6}	2.3

substituted phenols. When the ionizable hydrogen of the —NH group at position 1 was replaced by ethyl, there was a loss of uncoupling activity. Thus, although 4,5,6-trichloro-2-trifluoromethyl benzimidazole gave 80 per cent uncoupling at 5×10^{-7} M, its *N*-ethyl derivative was inactive at a concentration of 1×10^{-6} M, which was near the limit of its solubility. The uncoupling activity of the phenols was shown by Parker⁶ to depend on their *pK*_a. Similarly, the activity of the 2-trifluoromethylbenzimidazoles increased as the *pK*_a decreased; thus for halogen substituted benzimidazoles (Table 1) increasing chlorine substitution resulted in a series in which the *pK*_a decreased progressively and the uncoupling activity increased. However, substitution of nitro groups in place of halogens sometimes reduced the uncoupling activity and caused some departures from this relationship.

Replacement of a 5-chloro substituent on the benzene ring by substituents such as amino, methyl and hydrogen which have been found to reduce herbicidal activity¹ also reduced the activity in uncoupling oxidative phosphorylation.

The 2-trifluoromethyl benzimidazoles which are the most effective herbicides¹ have been found to be extremely active as uncouplers of oxidative phosphorylation. Tetrachloro-2-trifluoromethyl benzimidazole appears to be one of the most active uncouplers yet described. It is therefore probable that this activity in uncoupling oxidative phosphorylation contributes to the herbicidal action. They are thus similar in many respects to the nitrophenols and halophenols.

Since this communication was submitted a similar report of the uncoupling activity of NH-acidic benzimidazoles has appeared (K. H. Buchel, F. Korte and R. B. Beechey, *Angew. Chem., Internat. Edit.*, **4**, 788; 1965). Their findings are in substantial agreement with our own.

REPLICATION AND THE ACTIVATION OF MUSCLE DIFFERENTIATION

By DR. PAUL PIETSCH and SUSAN B. MCCOLLISTER

Biochemical Research Laboratory, The Dow Chemical Co., Midland, Michigan

THE investigation recorded here was conducted to test the possibility that myogenesis can be detonated in events associated with cell replication. The work was facilitated by the antibiotic phleomycin¹, which has the unique property of being able to inhibit DNA synthesis without interfering directly with the production of proteins or RNA^{1,2,18}. Phleomycin, like actinomycin D, appears to owe its specificity of action to selectivity in its binding with DNA. It appears to have an affinity for polynucleotides rich in A-T base pairs and it cancels DNA polymerase activity at concentrations that do not interfere with RNA polymerase². Regeneration in mouse skeletal muscle³ was selected as the principal test system because reasonably close approximations could be made of the time of appearance of the first wave of new muscle fibres or myotubes (96–120 h⁴), and of the interval during which replication takes place (38–72 h⁴). Also, because regeneration is not spontaneous in healthy skeletal muscle, but ensues as an almost inevitable consequence of non-fatal injury, it was possible to gauge the timing of events from a fairly precise starting point—much more so than with other specific myogenic systems (for example, the embryo, regenerating amphibian limbs, rhabdomyosarcoma, etc.).

DNA synthesis during the second–third day of regeneration. When the investigation was begun it was known that increased cell division takes place between the second and third day after injury⁴, but more detailed knowledge of this interval was required in order to undertake the present study. Therefore, the bellies of left tibialis anteriors in C57BL/6J (ref. 5) male mice sharing the same birth-date were inflicted aseptically with three puncture wounds using an 18-gauge hypodermic needle. Animals, weighing $20.1 \text{ g} \pm 0.2 \text{ S.D.}$, received 29 μCi tritiated thymidine (6,700 mc./mmole) intraperitoneally at specific times between 38.5 and 72 h. Injections were accomplished with an automated device, the dose being regulated by duration of infusion. The intervals for wounding and for injection among individuals in a given group of ten or so mice were kept within 3–5 min. At death, 40 min after pulse labelling⁶, the tibialis anterior was dissected out and DNA extracted differentially in 1.1 N perchlorate⁷. DNA was assessed quantitatively and qualitatively by ultra-violet absorption and radioactivity was measured by liquid scintillation

counting. The size of each muscle was accounted for on the basis of its total protein determined by the biuret reaction. Independent experiments were conducted to ascertain errors which might arise from differences in wound sizes. This was done by inflicting a single puncture in one tibialis anterior and three punctures in its contralogue. A correlation of 0.99 was obtained in DNA and actomyosin synthesis for right and left muscles in these cases, suggesting that the reaction would be all or none within the range of traumatization used in these investigations.

There are three waves of thymidine incorporation between 38.5 and 72 h post-wounding (Fig. 1, I, II and III). Peaks and profiles for I and III were confirmed in two independently executed studies. Wave II also was obtained in two separate series, but its peak and period varied by some 2 h. Wounds for all groups had been inflicted at approximately the same time of day, and, of

Fig. 1. Incorporation of tritiated thymidine at various times after wounding in tibialis anterior muscle. Unadjusted mean values are represented by the heavy line, and their standard deviations are shown by stippling. Dotted lines at wave III represent values corrected for circadian rhythm. Dashes indicate extrapolations through regions of overlap to the threshold line, that is, the level below which activity is not related to the waves *per se*. Areas under waves I and III were integrated after fitting their respective curves by least squares. The fitted curve for wave I was expressed by the equation: $y = 8.05069149X - 0.00143509987X^2 - 225.365393$; and for III: $y = 31.2881719X - 0.00254415843X^2 - 1,326.22411$. The computer rejected values when they were rounded off. There were from 6 to 10 individual cases per point in this experiment. In an earlier series with three cases per point the same profiles were obtained for waves I and III, but II varied

Table 1. EFFECTS OF CIRCADIAN RHYTHM ON INCORPORATION OF TRITIATED THYMIDINE DURING MOUSE MUSCLE REGENERATION

Wave (cf. Fig. 1)	n	*AZT 1 (activity $\times 10^4$)	n	AZT 7* (activity $\times 10^4$)	n	AZT 19* (activity $\times 10^4$)
I (38.5 h)			8	2.35 \pm 0.86 S.D.	7	2.67 \pm 0.99 S.D.
I (42 h)	8	1.77 \pm 0.38 S.D.	7	2.31 \pm 0.48 S.D.	4	2.26 \pm 0.34 S.D.
III (62 h)			5	7.00 \pm 2.72 S.D.	8	4.76 \pm 1.84 S.D.

While wave I shows no influence on thymidine incorporation that may be ascribed to circadian rhythm, it has been observed that constant exposure to light for prolonged periods does produce effects during this post-wounding interval. It is also noted that while wave III cells incorporate more thymidine at the high point in light, splenic cells show greatest uptake at maximal darkness (AZT 19).

* AZT, arbitrary Zeitgeber time, AZT 1 representing the onset of 12-h period of light.

necessity, the time of day at which tritiated thymidine was introduced varied for each point. This opened the possibility that circadian rhythm would influence wave amplitudes. Therefore, investigations were conducted with wounds (38.5, 42.0 or 62.0 h) receiving tritiated thymidine at different hours of the day. Routinely, all mice are maintained in a windowless, air-conditioned room and are exposed to consecutive, alternating 12-h periods of light and darkness, and this, of course, was maintained in the experiments under immediate consideration. It was learned (Table 1) that wave I (38.5- and 42-h wounds) is not influenced by the light rhythm employed in this laboratory. On the other hand, tritiated thymidine uptake at wave III was influenced by the time of day at which pulse labelling was carried out, for 62-h wounds that had been pulsed at the high point in light showed significantly more activity than did wounds of the same age pulsed at the maximal point in darkness.

These results indicated that, in order to approximate the true characteristics of wave III, it would be necessary to correct for the time of day of injection. In the experiments dealing with circadian rhythm, the arbitrary Zeitgeber time scale (AZT 1-24) suggested by others⁸ was used. In this scheme AZT 1 represents the time when lights go on and AZT 7 (1400 E.S.T. in this laboratory) and AZT 19 the high point in light and darkness, respectively. Such a scale has the obvious advantage over clock time of being readily reproducible anywhere in the world and at any season of the year. It was postulated that AZT 7 would represent the time of maximal operation of circadian factors; in other words, this time was taken as infinitely ideal with respect to increments of enhancement from light, and accordingly this time was assigned a value of zero along the x -axis (because zero steps of progression would be required to achieve it). AZTs were paired reciprocally between 7 and 19 and each set was assigned a consecutively ascending value from zero to twelve (thus $7/7 = 0$, $9/5 = 2$, $19/19 = 12$, etc.). Each set-value corresponded to the numbers of steps along the x -axis from the ideal time and each would represent $x/12$ universe along this axis. Unity was assigned to the y -axis at the ideal point ($x = 0$) and zero to the infinitely non-ideal time of $x = 12$ (AZT 19); that is, infinitely non-ideal time would have zero increments of help from circadian rhythm. Furthermore, it was postulated that circadian factors would decay from the infinitely ideal towards the infinitely non-ideal in an exponential manner. Thus, experimentally obtained values for wave III could be idealized or corrected for circadian rhythm by $R/e^{-x/12}$, R being the observed specific activity and x the set-value for the AZT at the time of pulse labelling. This correction was applied to values for wave III (with x greater than 0 in each case) in Fig. 1 (dotted lines). The applicability of the correction factor was determined by computing $\Delta 40-42$ h/ $\Delta 62-64$ h values from corrected curves and comparing this ratio with that obtained from cases with contralateral tibialis anterioris presenting I and III wave wounds at pulse labelling. The latter ratio was 0.382 and the corrected one 0.372. The corrected wave III curve proved extremely useful in determining the length and period of wave III and also in establishing a base-line for activity of the waves *per se*; that is, it was possible to extrapolate through regions of overlap and to obtain a

truer estimate of background values. On the basis of information to be described in the next section (cf. Tables 2 and 3) of this article it was learned that wave III terminates a little short of 68 h, and extrapolating to this point from the descending shoulder of the corrected curve for this wave, it was possible to traverse regions of activity that could not be handled empirically. The base-line generated horizontally to the left from 68 h intersected the ascending segment of wave I at about 38.5 h, providing an approximation for the onset of its period. After having dropped the point at 48 h to the base-line (once more on the strength of evidence presented in Tables 2 and 3), it was possible to idealize the curve for wave I. This was done by the least-squares method with a Burroughs 5,000 digital computer for waves I and III which produced the equations represented in the legend to Fig. 1. Areas under corrected curves turned out to be 27,000 units for wave I and 34,000 for III. Thus, wave I appears to begin at approximately 38 h and to end just short of 48 h. Wave III spans the interval between 60 and 68 h. The length of wave III, based on corrected expressions, turned out to be almost identical to the time established rather masterfully by others for the s -phase (DNA synthesis interval) in replicating mouse cells⁹. The approximately 10-h length of wave I, 3 h in excess of published s -phase values, no doubt represents asynchrony in the population plus inaccuracies of extrapolation. Interestingly, the similar areas under the curves for waves I and III indicate that the total amounts of DNA being synthesized are of roughly the same magnitude during these two periods, despite amplitude differences. Owing to these uncertainties, wave II was not evaluated.

Effects of phleomycin. With knowledge of the waves of DNA synthesis, their lengths, periods, peaks and characteristics during the important 2-3-day interval, it was possible to investigate the effects of phleomycin with respect both to actomyosin synthesis and DNA replication. Actomyosin synthesis was judged by the incorporation into this protein complex of L-lysine-¹⁴C (u.l. 223 mc./mmole) given intraperitoneally in two doses of 10.0 μ c. each at 94 and 117 h after wounding. At death, seven days after wounding, the entire tibialis anterior muscle was dissected out and actomyosin extracted in buffered 0.6 M potassium chloride^{10,11}. Concentration of actomyosin was determined from its ultra-violet absorption maximum (275 m μ), after the Folin reaction. Size of starting material was judged by determining non-fibrillar protein content of the sample. Radioactivity was measured by liquid scintillation counting. Uninjured muscle was processed similarly in order to develop a base-line for radioactivity not attributable to newly synthesized actomyosin. Phleomycin (kindly supplied by Bristol Laboratories, Syracuse, New York) was dissolved in physiological saline just prior to use, and its biological activity was confirmed on agar-plates seeded with *A. aerogenes*. Phleomycin (0.25 mg) applied before wounding (minus 13 h) or at the very end of waves I and III (48 and 68 h, respectively) failed to suppress actomyosin synthesis (Table 2). When the antibiotic was applied around the peak of wave III activity was moderately suppressed. However, phleomycin virtually eliminated actomyosin synthesis when it was administered to animals between 44 and 45 h; that is, on the descending shoulder of wave I.

The effects of phleomycin on DNA synthesis (Table 3) were judged after a single intraperitoneal dose of the antibiotic (0.5 mg) followed 1 h later by 29 μ c. tritiated thymidine. Animals were killed 40 min later, and tissues were processed in the manner described in the last section. As might be expected from the foregoing account, thymidine incorporation was severely depressed when phleomycin was given during wave I. Incorporation was also markedly suppressed when phleomycin was given during wave III, suggesting that, although these cells are influenced by the antibiotic so far as DNA synthesis is concerned, their future capacity to manufacture muscle proteins is un-

Table 2. TIME-DEPENDENT EFFECTS OF PHELOMYCIN ON ACTOMYOSIN SYNTHESIS IN REGENERATING MOUSE MUSCLE

impaired. When the antibiotic was given at minus-17 h there was no evidence of curtailed thymidine incorporation at wave I. Similarly, phleomycin at 59 h failed to suppress DNA synthesis at wave III. Phleomycin did not suppress activity when given during wave II; but it is emphasized that there is uncertainty concerning the exact period of this wave; consequently the significance of wave II remains obscure, and for reasons of economy and simplicity it has not been considered further.

Different responses to phleomycin. The pattern of suppression of DNA synthesis in regenerating muscle by phleomycin was not, *a priori*, completely predictable. It was expected, for example, that the antibiotic would influence DNA synthesis at almost any time up to the end of the process. Its failure to do this may have three interesting and not necessarily incompatible explanations: (a) the antibiotic might have restricted access to DNA except in rather circumscribed conditions; (b) the nucleotide sequences where the antibiotic makes its union may have a different operational significance in replication of various cell types; (c) the nucleotide sequences where phleomycin attaches to DNA may be dissimilar among unlike cells; that is, different 'genes' may be involved in binding in varying circumstances. Each of these explanations might underlie the relationship of replication to the read-out of muscle information; each suggests *de facto* differences during replication in unlike cells, and each leads to a single readily verifiable proposition, namely, that specific cell types shall respond differently to the antibiotic. With this in mind, animals were treated with phleomycin and 1 h later they, and a group of untreated siblings, were pulsed with tritiated thymidine. Comparison of specific activities of testicular DNA from treated and untreated mice showed no essential differences (correlation of 1.000). Similar studies were conducted with spleens (Fig. 2, legend) which, like testes, showed no short-term responses to the antibiotic. In another series with spleens (Fig. 2) pulse labelling was delayed until some 18 h after injection of phleomycin, and under these conditions DNA synthesis was suppressed but not altogether inhibited. Evidently some splenic

Fig. 2. Effects of phleomycin on incorporation of tritiated thymidine into splenic DNA when pulse labelling was delayed until approximately 24 h after administration of the antibiotic. In a separate series with spleens, tritiated thymidine was given 1 h after various doses of phleomycin. A dose of 0.5 mg/g body-weight produced specimens with specific activities of 10^4 . Spleens of animals that received 1.0 and 1.5 mg/g showed activities of 7×10^3 and untreated control values were 8×10^3 . Thus, the initial effects of phleomycin are not manifested immediately in splenic DNA synthesis. However, as seen in the experiments represented in this graph, a concentration-dependent response to the antibiotic is detectable when tritiated thymidine injection is delayed. In the graph, concentration of antibiotic is represented per gm body-weight along the x-axis.

cells are responsive to phleomycin but at any given moment they represent such a small minority of the total population that it is only after a significant time lapse that their absence from DNA synthesis is amplified to the point where it is detectable. (It seems possible that the responding cells are lymphocytic stem cells.) In a limited number of additional experiments, phleomycin was introduced into animals bearing one of the following transplantable mouse tumours: rhabdomyosarcoma (BW10139), myeloid leukaemia (C1498), adenocarcinoma (BW10232), melanoma (B16) (ref. 5). Tritiated thymidine was injected into treated and untreated tumour hosts 1 h after introduction of the antibiotic. Animals were killed 40 min later and for each the ratio of specific activity between tumour and splenic DNA was computed and compared. Only the phleomycin-treated rhabdomyosarcoma (muscle tumour) showed inhibition; that is, a significant increase in splenic thymidine incorporation as compared with untreated tumour/spleen ratios (Table 4).

In the other cases, tumour/spleen ratios, treated versus untreated, showed insignificant differences, suggesting that, like spleens and testes but unlike regenerating muscle and muscle tumour, there was no immediate, frank reaction to

Table 4. SHORT-TERM EFFECTS OF PHELOMYCIN ON TUMOUR/SPLEEN* RATIOS OF TRITIATED THYMIDINE INCORPORATION

Rhabdomyosarcoma	1	0.329	1	0.159

* Spleen does not show an immediate response to phleomycin (see legend, Fig. 2).

Treated and control spleens showed radioactivity within the same range. It is noted that phleomycin produces suppression in splenic DNA synthesis after about 24 h.

phleomycin by leukaemia, carcinoma or melanoma cells. Despite the prediction that this would happen, it must be recognized that testes and spleens are subject to individual physiological variations among animals and the same might very well have been true of tumours; thus, because of this the frame of reference might have been variant. Therefore, more exacting conditions were sought to provide a final test of the proposition. While cells of both waves I and III are highly susceptible to phleomycin, their different causal relationships to actomyosin synthesis suggested, intuitively, that they would vary mutually in response to this antibiotic.

Owing to large standard deviations in data from different individual mice (Fig. 1) it was impossible to design a statistically efficient experiment based on anticipated small comparative differences. It was decided, therefore, to use both tibialis anterior muscles in the same animal, to vary the times of wounding and thereby to make available to wounds of different ages an otherwise uniform set of conditions. Specimens were compared on an individual basis for each animal, the information sought being the comparative value between mean ratios of treated versus those for untreated individuals. The premise was that if phleomycin influenced wounds on both sides of the animal in the same way, then, while absolute values might differ, the ratios would fall within the same statistical range. Conversely, if cells respond in an unlike manner to the antibiotic the ratios between contralateral wounds would differ between treated and untreated. Two series were conducted, 41/63 and 41/43, numerators and denominators representing the ages of the wounds when phleomycin was introduced. Untreated 41/43 ratios showed a mean (four cases) of 0.827 ± 0.27 S.D.; means (five cases) for 41/43 phleomycin-treated animals were 0.873 ± 0.27 S.D., indicating no difference in response to the antibiotic at the two points along wave I. In 41/63 h experiments untreated ratios (seven cases) were 0.382 ± 0.20 , but phleomycin-treated specimens revealed ratios (eight cases) of 0.638 ± 0.18 S.D.; that is, differences between the two groups of very high significance (F distribution beyond 1 per cent).

Thus, phleomycin can virtually eliminate myogenesis but only when it is made available during a critical time-interval. In mouse skeletal muscle regeneration in particular this interval coincides with the period of wave I. As is true with other agents which inhibit regeneration, there is a close correlation between the events going on at the time of application and the mode of inhibitory action (see review of these in Fig. 3). A phase comparable to wave I seems required to set myogenesis into motion, and this appears to entail at least one round of DNA synthesis. Further division may occur but it is not mandatory. It has been reported of tissue-cultured myoblasts that they need not divide in order to accomplish differentiation^{12,13}. Judging from the advanced age of embryonic donors in the last-cited experiments, the cultivated cells, doubtless, had passed the point equivalent to wave I prior to explantation.

Obviously the channels to muscle information are not opened merely by genomic duplication (otherwise all dividing cells would produce muscle) and obviously DNA synthesis cannot be regarded as the proximate cause of myogenesis. Indeed, the nature of wave I's contribution remains to be established. During regeneration also, there is a significant time lapse between wave I and mRNA synthesis (at about 72 h (ref. 14)) and it is fairly well established that when DNA synthesis is going on actomyosin synthesis is not¹⁵. While it is much simpler to regard wave I as the immediate source of myogenic cells the possibility should not be ignored that the wave supplies information that is utilized by other cells.

Differential susceptibility of wave I and III cells (as well as cells of other types) to phleomycin suggests that

Fig. 3. Summary of time-dependent inhibition of various agents on muscle regeneration and the major events that occur during the sensitive interval. References: colchicine⁴, X-rays¹¹, actinomycin D¹⁴.

specificity in the operational features of thymidine incorporation during wave I, at the molecular or chromosomal level or both—the specific information that may become readable as a result of the uniqueness of factors bestowing differences—may determine the kind of future the daughter cells shall have, whether they shall divide again or enter into relative dormancy or begin to synthesize, anew, polymeric classes previously not among the cell's complement. It seems quite possible, carrying this line of speculation a little further, that the release of specific information could in principle be a function of detailed firing orders among chromosomes, polynucleotide sequences, or both, with read-out being a consequence of the order in which elements were reproduced, and not the gross fact of duplication. If such a method of release is true of myogenesis, then it seems likely that there are other examples of differentiation in which details of replication play an important part. This possibility suggests that it would be quite worth-while to gain comprehensive knowledge concerning the physical chemistry of phleomycin-DNA complexes in different cell types. Indeed, the decision to include these few speculations at all was reached only because technology exists for determining the kinds of interactions possible between this very valuable antibiotic and deoxypolynucleotides.

⁶ Within a few minutes of intraperitoneal injection of tritiated thymidine into mice, their urines became highly radioactive. Within 1 h activity falls to a fraction of this value, approaching background levels. Splenic biopsies 15 min after injection show a level of activity that is maintained in biopsies taken 30 and 90 min later. Thus, it would appear that label is available for a brief interval after administration and that a single injection closely approximates a pulse. These observations were made by Strossberg and Pietsch, 1962 (unpublished), and incidental to the present investigation.

NOREPINEPHRINE AND SEROTONIN IN THE TISSUES AND VENOMS OF TWO PIT VIPERS

By PROF. AARON H. ANTON and PROF. JOSEPH F. GENNARO, jun.*

Departments of Anesthesiology, Pharmacology and Anatomy, College of Medicine, University of Florida, Gainesville

THE serotonin and catecholamine content of snake venom is of interest because of their possible contribution to the profound vascular changes and pain produced by this toxic substance. Venoms which have a defensive use, such as those of insect origin, have been found to contain serotonin, the quantity of which has been said to be directly related to the pain-producing ability¹⁻³. Zarafonitis and Kalas⁴ have implicated these materials in the skin slough and the necrotic lesions produced by reptile venoms because such damage has also occurred after the injection of serotonin and epinephrine. In their work, the authors mentioned that these amines were detectable only from specimens of reptile venom frozen in a dry-ice bath immediately after collection and thawed just prior to testing. They were unable to detect serotonin from the lyophilized venom which is used for the production of antivenin. Because of the implication that lyophilized venom, the preparation commonly used in most researches into the biochemical, physiological and immunological properties of reptile venom, does not contain materials present in the natural state, these observations required confirmation. Hence, several tissues of two species of poisonous snakes as well as their venom collected under various conditions were analysed for norepinephrine and serotonin.

The venom glands were excised and pooled from two specimens each of the Eastern diamondback rattlesnake (*Crotalus adamanteus*) and the cottonmouth moccasin (*Agkistrodon piscivorus*). Large snakes were anaesthetized with intraperitoneal injections of sodium pentobarbital (1-5 ml. of an isotonic saline solution containing 60 mg of barbiturate per ml.) and the venom gland was carefully dissected on each side of the head. Clamps were fixed to the venom ducts to prevent the expression of venom, and the glands of each species were pooled separately in glass dishes kept on ice before homogenizing for analysis. While still anaesthetized various tissues were removed and frozen until analysed for norepinephrine and serotonin.

Fresh venom was collected for analysis from other snakes of the same species into beakers containing 5 mg of β -phenylisopropylhydrazine ('Catron'), a monoamine oxidase inhibitor, and packed in dry ice. For collection of venom the fangs were hooked over the edge of a vessel and the snakes were allowed to bite and eject venom naturally. Little or no pressure was placed on the venom gland during this process as is sometimes done in the 'milking' of venom commercially. Venom was also collected from these two species into Dewar flasks filled almost to the top with liquid nitrogen. Venom ejected into the nitrogen bath was instantly frozen into small droplets which sank to the bottom of the nitrogen pool. The entire container was then transferred to a vacuum chamber and the venom was lyophilized. At no time before dryness did the temperature of the frozen droplets approach ambient temperature.

Catecholamines⁵ and serotonin⁶ were measured fluorometrically after extraction from tissues.

The tissue distribution of norepinephrine (NE) and serotonin (5-hydroxytryptamine, 5-HT) in these snakes is shown in Table 1. NE was detected in all tissues examined, including the venom gland, but not in any of the venom preparations. 5-HT, on the other hand, was found only in the brain of both species, and in the spleen of the rattlesnake. As with NE, no significant amounts

Table 1. TISSUE NOREPINEPHRINE (NE) AND SEROTONIN (5-HT) IN SNAKES
Results are from pooled samples from at least two specimens of each species. Figures in parentheses mean that the fluorescence spectra of these samples were not the same as the serotonin control. Kidney epinephrine of both species was about 50 per cent of the norepinephrine content, the spleen epinephrine of the cottonmouth was about 25 per cent of that of the norepinephrine whereas the other tissues contained insignificant amounts of epinephrine

Tissue	Cottonmouth, $\mu\text{g/g}$		Rattlesnake, $\mu\text{g/g}$	
	NE	5-HT	NE	5-HT
Brain	0.93	1.77	0.44	2.70
Heart	0.64	(0.24)	0.82	(0.06)
Kidney	0.98		0.82	
Liver	0.10	(0.29)	0.24	(0.06)
Lung	0.10		0.20	
Spleen	0.43	(0.18)		1.65
Poison gland	0.72	(0.29)	0.23	(0.63)
Venom:				
Lyophilized	<0.01	(0.03)	<0.01	(0.04)
Fresh milked	<0.01	(0.03)	<0.01	(0.04)
Stored milked	<0.01	(0.03)	<0.01	(0.04)

of 5-HT were found in any of the venom extracts, not even in the specimen collected in the presence of the monoamine oxidase (MAO) inhibitor. The inhibitor was used to prevent the possible destruction of the amines by the MAO that reportedly is present in the venom of these snakes⁴. It should be mentioned that we did not detect MAO, catechol-*o*-methyltransferase or 5-HT/DOPA decarboxylase in the venom or poison gland of the rattlesnake⁷; these enzymes are concerned with the metabolism of NE and 5-HT. However, a contaminating fluorescent substance was extracted from the tissue and venom of these snakes by the procedure that was used for 5-HT, and this is shown in Fig. 1. It can be seen that the fluorescence characteristics of authentic 5-HT and the brain extract are similar, whereas they are dissimilar in the case of the extracts from the poison gland and venom. Although the activation spectrum of the venom extract is shifted only slightly to the left of that of the 5-HT standard, the fluorescence spectrum lies completely out of the range of that exhibited by 5-HT. No differences were noted in the fluorescence produced by venoms which were prepared by

Fig. 1. Fluorescence characteristics of extracts from brain, poison gland and venom of the rattlesnake compared with authentic serotonin (5-HT)

Fig. 2. Fluorescence characteristics of rattlesnake poison gland extract compared to authentic norepinephrine (NE)

lyophilization, or assayed immediately after removal from the snakes or were immediately frozen and assayed at a later time. In neither species studied here was this fluorescence the same as that of authentic 5-HT.

As shown in Fig. 2, the fluorescence characteristics of authentic NE and the substance extracted from the venom gland also were compared. In this case the spectra are identical, indicating that norepinephrine is present in the gland as well as that the analytical procedure for NE is more specific than that for 5-HT.

Norepinephrine was found to be distributed in the tissues of these snakes in a manner similar to that in other animals. Relatively large amounts of NE as well as serotonin were found in brain. This suggests a possible neural function for these amines in the peripheral and central nervous systems of these species analogous to that suggested for other animals. Finding NE in the poison gland may reflect some role in the function of this organ. On the other hand, 5-HT was not detected in the poison gland, and neither amine was found in the venom of these snakes as was reported by Zarafonitis and Kalas⁴. The reason for this discrepancy is probably one of methodology. We have found the Al_2O_3 -trihydroxyindole procedure for catecholamines to be much more specific⁸ than the organic solvent extraction method⁹ used by Zarafonitis

and Kalas. An organic solvent extraction procedure for 5-HT was also used by these workers and ourselves; but our results indicate the presence of a contaminating fluorescing material in venom and the venom gland which could be mistaken for 5-HT. Ordinary 'milking' procedures used to obtain reptile venom traumatize the glandular tissues, and thus could release cells and cellular constituents rich in this unidentified, highly fluorescing substance into the specimen being collected.

Other investigators either regard the minute amounts of these amines, which may be present in snake venom, as being insignificant, or have actually failed to detect their presence^{10,11}. In this respect, workers who have investigated the role of 5-HT in arthropod venom, where it appears in quantity, have found that the removal of this material does not alter the toxicity of the remainder¹². This has led to their questioning the biological significance of 5-HT in such venom¹³. Welsh and Batty have concluded that 5-HT, which can exist in very large quantities in the venom of arthropods and insects, may play a part in defence (as pain-producers), though they cite examples of scorpions, stinging ants, and solitary wasps which produce painful stings and do not contain 5-HT (ref. 3).

Therefore, it seems unwarranted at the present time to conclude that the possible presence of minute amounts of serotonin and norepinephrine contributes significantly to the profound tissue damage caused by the necrotizing and haemorrhagic principles which have been found in the venom of these snakes¹⁴.

FRACTIONATION OF MOUSE DEOXYRIBONUCLEIC ACID ON HYDROXYAPATITE

By DR P. M. B. WALKER

Chemical Biology Unit, Department of Zoology, University of Edinburgh

AND

DR. ANNE McLAREN

Agricultural Research Council Unit of Animal Genetics,
Institute of Animal Genetics, Edinburgh

WE have been examining the ability of various fractions of mouse DNA to form specific duplexes with homologous or heterologous DNA in agar^{1,2}. One particularly convenient method of obtaining fractions which differ either in their degree of secondary structure or in their base composition is by the use of hydroxyapatite columns^{3,4}. The results which we have obtained with such fractions may provide evidence concerning both

the hydroxyapatite fractionation procedure and the organization of mouse DNA.

DNA extracted from mouse livers or from mouse L-strain cell cultures¹ is heated for 10 min at 100° C in either 1.5×10^{-3} M sodium chloride and 1.5×10^{-4} M sodium citrate or 3×10^{-3} M phosphate buffer, pH 6.5, and is then cooled in ice water. Chromatography of this material on hydroxyapatite at a constant temperature

with increasing phosphate concentration yields two fractions (Fig. 1): a minor fraction, which at any given temperature of fractionation elutes at a salt concentration similar to native DNA, and a major fraction, which elutes at a lower salt concentration. We shall refer to these as the 'stable' and 'labile' fractions respectively. If the stable material is refractionated under the same conditions, it elutes at the same salt concentration (0.2 M) as before; if it is denatured again before refractionation, it still elutes at the same 0.2 M phosphate position, with only a minor component at the 0.1 M position (Fig. 2b). None of the labile fraction elutes at the 0.2 M phosphate position after a second fractionation (Fig. 2a). In subsequent experiments, the salt concentrations were changed

stepwise, so as to facilitate the recovery and characterization of the fractions. Fig. 3a shows a stepwise elution pattern for a sample of DNA disrupted by ultrasound and fractionated on hydroxyapatite at 70° C. In the stepwise procedure, DNA which elutes at 0.2 M on a gradient will appear between 0.15 and 0.3 M, that is in the 0.3 M washes.

Nature of the stable fraction. The fractionation of denatured DNA on hydroxyapatite depends on the presence of secondary structure, which is stable at the particular temperature at which the columns are run. It is therefore complementary to the thermal elution chromatography procedure also described by Miyazawa and Thomas³, in which native DNA is eluted as a function of temperature at a constant salt concentration. In the latter procedure, the fragments elute as soon as they melt, and it has been shown³ that the lower temperature fractions are rich in adenine and thymine (A + T), and the higher fractions in guanine and cytosine (G + C).

We have compared the two procedures directly by first fractionating native DNA by the thermal elution method, and then re-running these fractions at a constant temperature with stepwise elution on hydroxyapatite (Fig. 4). Those fractions melting at the highest temperatures contained the largest proportion of DNA eluting between 0.16 and 0.3 M phosphate.

Although the stable fraction elutes in the native position, it is not identical with native DNA. The most striking demonstration of this is seen in its ability to form stable duplexes with high molecular weight mouse DNA trapped in agar gels⁵. The high binding ability of the stable fraction is the more surprising since melting curve experiments confirm that it is at least partially duplex in structure. Fig. 3b shows thermal melting curves for stable and labile fractions from a 70° C hydroxyapatite fractionation. The two fractions have a very different melting behaviour: the labile DNA shows a typical 'single-stranded' melting profile, similar to that of RNA, while the stable material more nearly resembles the native material (curve ●, Fig. 5), though its mid-point of melting (T_m) is 5.5° C lower. Its lower T_m , together with the wider range of temperature over which it melts, indicates presumably that the reformed duplexes are less perfect than the native.

The proportion of sonically disrupted DNA eluting as a stable fraction increases as the temperature of fractionation is lowered from 70° C to 20° C. Fig. 5 compares the

Fig. 1. Fractionation of sonically disrupted and denatured DNA on hydroxyapatite at 70° C. Phosphate gradient increases continuously from 0.03 to 0.3 M

Fig. 2. a, Major fraction from fractionation shown in Fig. 1 re-run; b, minor fraction re-run after a second thermal denaturation. All other conditions as Fig. 1

melting curves of stable fractions obtained at five different temperatures with native DNA of a similar molecular weight distribution. From the 20° C and 40° C fractionations, about three-quarters of the stable material melts gradually below 60° C. The increase in size of the stable fraction as the temperature of fractionation is lowered must, therefore, be due to the inclusion of single-chain molecules, eluting at higher salt because of the secondary structure which forms in single-stranded material on cooling. A corollary of this is that any DNA fraction

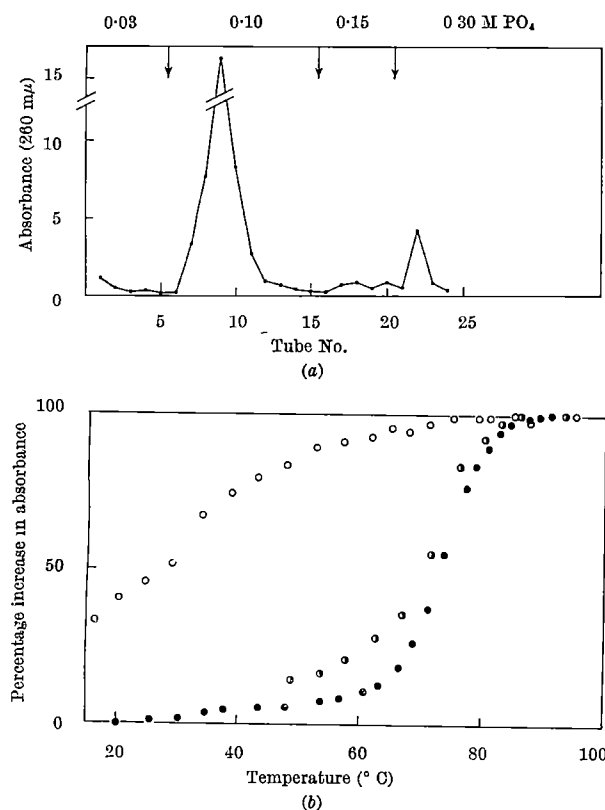

Fig. 3. *a*, 70° C stepwise elution chromatogram of sonically disrupted and denatured DNA, *b*, melting curves of fractionated DNA illustrated in *a*. ○, 0.1 M fraction; ●, 0.3 M fraction, first cycle; ◐, 0.3 M fraction, second cycle. All curves normalized to 100 per cent. Percentage increase in absorbance between 20° and 95° was 19.4 and 32.1 for the 0.1 and 0.3 M fractions respectively. All absorbances recorded in this article are at 260 mμ, and all melting curves are measured in 0.1 M NaCl and 10⁻⁴ cacodylate, pH 6.4

Fig. 4 Thermal elution chromatogram of mouse DNA in 0.08 M phosphate (○), and the percentage (●) of the indicated fractions (brackets show pooling) which eluted between 0.16 and 0.30 M phosphate on a subsequent salt gradient chromatogram at 70° C

Fig. 5. Comparison of the melting curves of denatured DNA which elutes between 0.16 and 0.3 M phosphate at different temperatures on hydroxyapatite. The temperature of fractionation and percentage increase in absorbance between 20° and 95° are as follows: ▲, 20° C, 21.8 per cent; □, 40° C, 28.8 per cent; ▽, 50° C, 30.2 per cent; ■, 60° C, 29.0 per cent; ○, 70° C, 32.1 per cent; ●, unfractionated, native, 35.7 per cent

with a base sequence or composition which prevents it from forming secondary structure should elute in the 0.1 M phosphate position at room temperature. Our mouse DNA contains no such fraction.

Rate of reformation of duplex structure. The degree of reversibility of a thermal denaturation curve gives some indication of the speed and efficiency with which ordered duplex structure can be reformed. In the experiment illustrated in Fig. 3*b*, after heating to 95° C the cuvettes were rapidly cooled with iced water. On again raising the temperature, the absorbance was found to be higher than its original 20° C value, by only 20 per cent at 20° C, and by 32 per cent at 49° C. After 4 h at 49° C, the percentage increase at this temperature had fallen to 16 per cent and fell little more during a subsequent 12-h incubation at 49° C.

When the solution was then reheated to 90° C, it gave a melting curve very similar to that obtained during the first cycle of heating (●, Fig. 3*b*). These results indicate that a considerable amount of the original ordered structure was almost immediately reformed on cooling, with some further reassortment of strands occurring during incubation at 50° C. This has been confirmed by other experiments in which the second-cycle melting curve followed the first almost immediately.

Evidence of cross-linkage. It appears, then, that the stable fraction from a 70° C hydroxyapatite chromatogram consists of material which elutes at a high salt concentration owing to the rapid reformation of duplex structure after denaturation. This might be expected: (a) if the DNA fraction were made up of relatively short sequences repeated many times, so that association of strands at any one of a number of points gave complementary sequences over an extended region; (b) if the DNA strands either failed to separate completely on heating or if they folded back on themselves from the single-stranded state on account of some special sequence of bases.

On the first hypothesis, rate of duplex reformation should be related to the DNA concentration; while on the

other hypothesis, it should be independent of concentration. We therefore determined whether the concentration at the time of denaturation affected the relative size of the stable fraction. In all cases, DNA solutions in 0.03 M phosphate buffer were heated in a boiling-water bath for 10 min and rapidly chilled in ice; two volumes of distilled water were then added and the DNA immediately adsorbed on to the hydroxyapatite. We found (Table 1) that the size of the stable fraction was affected neither by the concentration at which the DNA sample was denatured nor by the amount of DNA that was put on the hydroxyapatite column.

This evidence might suggest that the strands are held in register by heat-resistant bonds. Our stable fraction may contain a high proportion of CG-rich nuclei (Fig. 4), which are known to resist melting at high temperatures⁶, but which are sensitive to alkaline denaturation⁷. When a sample of DNA was denatured by raising the pH to 12.4 for 10 min at 18° C, the size of the stable fraction was unaffected (Table 1). It therefore seems unlikely that the thermal stability of the CG-rich regions is responsible for holding the strands in register.

Table 1. THE EFFECT OF CONDITIONS DURING DENATURATION ON THE PROPORTION OF DNA ELUTING BETWEEN 1.5 AND 0.3 M PHOSPHATE

Denaturation treatment	DNA concentration during denaturation ($\mu\text{g/ml.}$)	Amount of DNA on hydroxyapatite column (μg)	% of radioactivity eluting between 1.5 and 0.3 M ('stable fraction')
Thermal	30	5	12.7
Thermal	70	12	11.0
Thermal	0.3	3	13.8
Thermal	0.7	0.12	9.2
Alkaline	30	4	8.3
Alkaline	30	4	9.3

Another possibility is that the strands are held together by covalent linkages. These, if present in nature, could be composed of protein. We therefore subjected our DNA before denaturation to digestion by the proteolytic enzyme, 'Pronase B' (Calbiochem Inc.), for 2 and 15 h at 37° C; but this had no effect on the size of the stable fraction.

Cross-linkages may be induced in DNA, for example by nitrous acid. Geiduschek⁸ reported that such cross-linked vertebrate DNA will renature almost completely, and

Fig. 6. Melting curves of nitrous acid-DNA. Δ , 0.03-0.12 M phosphate fraction; \circ , 0.12-0.16 M phosphate fraction; \bullet , native DNA. All were from the same batch of sonically disrupted DNA.

Fig. 7. Melting curves of sheared and high molecular weight DNA. \circ , 0.03-0.10 M, sheared DNA, 20.3 per cent; \square , 0.15-0.30 M, sheared DNA, 26.6 per cent; \bullet , 0.03-0.10 M, high molecular weight DNA, 20.2 per cent; \blacksquare , 0.15-0.30 M, high molecular weight DNA, 21.6 per cent. Numbers refer to molarity of phosphate. The percentages refer to the overall increase in absorbance.

that only a small fraction of the amino groups need be cross-linked to allow this renaturation to occur. Since our stable fraction not only has a T_m 5.5° C lower than that of native DNA, but is also able, unlike native DNA, to form stable duplex molecules with denatured DNA in agar, it cannot be the completely helical molecule which Geiduschek's results might lead one to expect. To investigate the properties of deliberately cross-linked DNA, we treated a sonically disrupted sample with nitrous acid, following Geiduschek's procedure exactly, then denatured it and subjected it to fractionation on hydroxyapatite. This treatment caused 60 per cent of the DNA to elute between 0.12 and 0.16 M phosphate, the remainder appearing between 0.03 and 0.12 M phosphate. The melting curves of these two fractions were strikingly different (Fig. 6), the high salt fraction showing a sharp melting transition 7.0° C lower than that of an untreated native sample of the same molecular weight distribution.

We also fractionated high molecular weight DNA, which had been similarly treated with nitrous acid, and found that all the DNA now eluted between 0.16 and 0.30 M phosphate. This DNA had a melting curve identical with the high salt fraction from the low molecular weight sample. The induced cross-linkages can therefore allow considerable lengths of DNA to renature which are not themselves cross-linked. As will be shown below, the stable fraction of DNA is unable to promote the complete renaturation of higher molecular weight samples.

To determine whether ultrasonic treatment of our DNA might have caused cross-linkages to form, we subjected to hydroxyapatite fractionation our high molecular weight DNA, and also DNA sheared by a single passage through a French pressure cell. The sheared material is trapped in a plain agar gel more readily than is the sonically broken DNA, and must therefore have a higher average molecular weight. On denaturation and subsequent hydroxyapatite fractionation at 70° C, the sheared DNA yielded stable and labile fractions with 0.3 M and 0.1 M phosphate respectively. The melting curve of the stable fraction gave a fairly sharp transition

between 65° C and 80° C (Fig. 7), but unlike the corresponding fraction from ultrasonically broken DNA, it also showed a gradual increase in absorbance between 20° and 60° C. The high molecular weight DNA gave a small stable peak eluting with 0.3 M phosphate, and also an intermediate peak with 0.15 M phosphate. The melting curves of the 0.1 M and 0.3 M phosphate fractions are much more like one another than are those of lower molecular weight DNA, but some evidence for a fairly sharp transition can still be seen at high temperatures.

We interpret these results to mean that at higher molecular weights the molecules which elute at the high salt concentration are partially single-stranded, a relatively short duplex section sufficing to stabilize the whole molecule on the hydroxyapatite. The small size of the 0.3 M fraction obtained from the high molecular weight preparation is probably due to the presence of long single-stranded regions in some of the molecules which also contain duplex regions. A high ratio of the single-stranded to duplex parts might cause them to elute at a lower salt concentration. As the molecular weight is reduced, a progressively larger proportion of each 'stable' molecule is in the duplex state, resulting in a much cleaner fractionation. These results do not support the view that the stable fraction consists of material in which cross-linkages have been induced by ultrasonic treatment.

Discussion. While it is clear that the fractionation of denatured DNA on hydroxyapatite depends on the presence of secondary structure, the method described in this article does not easily distinguish between native DNA, and duplex molecules of stabilities ranging from those melting gradually below 60° C to those showing a sharp thermal transition like that of the native structure. All these can elute from the columns at a phosphate concentration near 0.2 M. The quality of the 0.2 M fractions of DNA, as judged by the shape of their melting curves, depends both on the molecular weight distribution of the initial preparation and on the temperature of fractionation. When these two factors are independently varied, the melting curves produced show a similar pattern, though for rather different reasons.

As we lower the temperature of fractionation, using sonically disrupted DNA of a constant molecular weight distribution, progressively more of the DNA fragments are able to form secondary structure and hence to elute at 0.2 M phosphate. Thus, each melting curve illustrated in Fig. 5 represents a heterogeneous fraction of molecules in which the proportion of the more perfect duplexes decreases with the temperature of fractionation. When DNA of differing molecular weight is fractionated at a constant temperature (70° C), the proportion of the more perfect duplexes again decreases, this time as molecular weight increases, but now the heterogeneity must be along the length of the molecules rather than between molecules. The additional regions must be capable of forming secondary structure at lower temperatures, which melts gradually as the temperature is increased to 60° C. Presumably in their single-stranded condition at 70°, they can be stabilized on hydroxyapatite by the more perfect duplexes to which they are attached.

Our comparison of the chromatographic behaviour of high molecular weight and ultrasonically treated DNA cross-linked with nitrous acid (Fig. 6), as well as earlier evidence⁸, suggests that the bridges which hold the two strands of denatured DNA in register will allow single strands to reform duplexes even if they are at a considerable distance from the bridge. Our stable DNA fraction appears to lack this property, since increasing the molecular weight causes less of the DNA to elute at high salt, and the molecules which do appear at high salt contain a considerable proportion of single strands.

Since the linkages which we believe to be responsible for the properties of the stable fraction are resistant to treatment with heat, alkali and 'Pronase', we are forced to consider models in which the covalent linkage is not

between the two strands of the double helical molecule. For example, the stable covalent bond might consist of a phosphodiester linkage between bases in a single DNA strand, such that the base sequences on either side would allow the strand to fold back on itself and form a duplex region like a hairpin. Discrepancies in the complementary sequences, and the random nature of the original double-strand scissions induced by sonic disruption, could then account for the lower stability of the duplex compared with the native molecule, and for the availability of sites for binding in the agar experiments. The effect of increasing the molecular weight would imply that the sequence restrictions only extend for a relatively short distance from the point of inflexion before becoming non-complementary.

The second model requires further assumptions. If the genome in higher organisms has more than one double helix of DNA per chromosome, then the semi-conservative nature of chromatid reproduction⁹ demands some mechanism for assorting the old and new strands. If covalent linkages joined corresponding halves of the helical molecule, denaturation would give one linked set of old and one of new strands. If the base sequences on either side of the linkages were restricted as in our first model, so as to allow duplex regions to reform, then this model also would explain the properties of stable DNA.

There is accumulating evidence that there may be what might be termed macro-heterogeneity in DNA from higher organisms, that is that there are sections or species of DNA which have properties sufficiently different from the rest to allow them to be isolated or identified. Such sections, which may have special genetic functions, may be sufficiently small to facilitate the eventual determination of base sequences.

The large size of the DNA fraction with the special properties we have been considering, together with the evidence that, in sheared and high molecular weight DNA, the fractions may be joined to other single-chain parts of the denatured molecule, would seem to preclude either cytoplasmic or viral DNA as the source of this fraction. It is also too large to be accounted for by the DNA sequences coding for ribosomal RNA¹⁰, although there is evidence from the structure of such RNA¹¹ that it might be coded by a DNA with similar sequence restrictions to those we have postulated for our DNA fraction. On the other hand, the 'satellite' bands of DNA separated by equilibrium density centrifugation from several mammals¹², including the mouse, are of the same relative size. The satellite band in the mouse is, however, lighter than the main band and probably has a higher AT content.

STIMULATION OF SYNTHESIS OF RIBONUCLEIC ACID IN SUB-APICAL SECTIONS OF *Avena* COLEOPTILE BY INDOLYL-3-ACETIC ACID

By PROF. T. H. HAMILTON, R. J. MOORE*, A. F. RUMSEY, A. R. MEANS and PROF. A. R. SCHRANK

Department of Zoology, University of Texas, Austin

FIG. 1 and its insert illustrate the well-known biological response of *Avena* coleoptile sections to the presence in culture medium of auxin or the plant hormone indolyl-3-acetic acid (IAA). This response represents one of increased growth (= cell elongation) rate over that which occurs in the absence of IAA. Time-sequence investigations (insert, Fig. 1) indicate that the differences in morphological responses between controls and IAA-stimulated coleoptile sections are particularly pronounced after the initial (8–10 h) period of hormone action. By 24 h the IAA-stimulated sections exhibit increases in length which are about 300 per cent greater than those of controls.

In recent years the involvement of RNA and protein synthesis in early hormone action has been demonstrated for a variety of animal¹ and plant² tissues. Furthermore, the inhibition of various biochemical and morphological responses to hormone by actinomycin D (ref. 3) has been interpreted as indicating the necessity for DNA-dependent RNA synthesis for complete manifestation of the biological response to hormone. These investigations^{1,2,4} have emphasized—implicitly if not explicitly—the problem of elucidating biochemical events which occur prior to the morphological ones during sequential responses of specific tissue to hormones. We have thus undertaken for *Avena* coleoptile an investigation of the effect of IAA on RNA synthesis during the initial 8-h period prior to full achievement of morphological response to the hormone.

We now report data which indicate a marked stimulation by IAA of the rate of synthesis of the major classes of RNA in sub-apical sections of the *Avena* coleoptile. We find this stimulation by IAA to be inhibited by actinomycin D. We interpret these observations to indicate that IAA in its early action indirectly or directly exerts an influence on some rate-limiting step in DNA-dependent RNA synthesis. Along with base compositions of total RNA and ribosomal RNA (rRNA), the data presented also provide a partial characterization of the ribosomes (80 S) and classes of rRNA (30 S and 20 S) of *Avena* coleoptile.

Seeds of *Avena sativa* L. (Victory strain: U.S. Department of Agriculture, C.I. 2020) were germinated and grown according to the method of Wiegand and Schrank⁵. After removal of the primary leaf, 5-mm sections of coleoptiles were cut, starting 5 mm below the tip. Absolute growth-rates at times indicated (Fig. 1) were determined by the taking of linear measurements to the nearest 0.1 mm by use of a dissecting scope equipped with an ocular micrometer. For the morphological responses and labelling experiments described as follows, all experimental conditions were identical.

In the course of this work, bacterial contamination of both culture media and cavities of coleoptile sections became evident. Thorough washing of coleoptile sections by the method of Glišin and Glišin⁶ proved partially successful, removing approximately 95 per cent of bacteria in cultures prior to the washings. For an antibiotic, penicillin, streptomycin, tetracycline, mycostatin, erythromycin, and kanamycin were tested. Bacterial levels of samples of culture medium and coleoptile homogenates were assayed by inoculation tests in brain-heart-infusion broth. Briefly stated, with exception of penicillin the antibiotics listed (when used in concentrations necessary for suppression of bacteria) had inhibitory effects either on morphological responses or on RNA synthesis (or

both) of coleoptile sections. Exposures to ultra-violet light—varying length of exposure, distance from source, and intensity of irradiation—were similarly harmful to control responses. Neither by antibiotics nor irradiation techniques have we been able to obtain a bacteria-free coleoptile system without also inhibiting the control responses to culture medium. For the purposes of the work recorded here, penicillin alone provided some protection, but even that resulted in only a slight reduction of bacteria number. We note here that there are no published reports of an effect of IAA on bacterial growth.

In all experiments, 200 coleoptile sections were incubated in 10 ml. of a standard medium (0.01 M tris-maleate, 2 per cent sucrose, 60 units/ml. penicillin GK) having a pH of 5.5 at 5° C. ³H-uridine (1.84 c./mmole) in amount sufficient to maintain linear incorporation for 24 h was added to the medium for a final concentration of 0.002 mM. IAA and actinomycin D, when used, were at final concentrations of 1×10^{-5} M (1.75 µg/ml.) and 8×10^{-6} M (10 µg/ml.). Incubations were carried out under dim red light in a water-bath shaker at 25° C. 8 h later, incorporations were stopped by rapid washing at 0°–2° C of the sections with 500 ml. of an acetate buffer (0.01 M NaAc, 0.1 M NaCl, 0.001 M MgCl₂; pH 5.0 at 5° C).

Coleoptile sections were homogenized at 0°–2° C by 20 strokes in 2 ml. of the acetate buffer in a glass-glass homogenizer run at 600 r.p.m. The homogenate was then adjusted to 1 per cent sodium dodecyl sulphate (SDS) and extracted with an equal volume of buffer-saturated phenol by vigorous shaking at 0° C for 3 min. The layers were separated by centrifugation, and the aqueous layer was extracted twice more with one-half and one-fourth volumes of phenol. Following addition of 2 vol. of cold ethanol to the final aqueous layer, RNA was precipitated

Fig. 1. Growth of *Avena* coleoptile sections as a function of time. Measurements are expressed as increases in length (over a base-length of 5 mm) from 0 to 8 h. Closed (▲) and open (△) triangles denote values for sections incubated in control medium and control medium with actinomycin D added. Closed (●) and open (○) circles denote values for sections incubated in the presence of IAA with actinomycin D absent or present. Concentrations of IAA and actinomycin D and conditions of incubation are described in the text. Insert shows schematically the trends we find for the four experiments run under the same conditions for 24 h. Increases here for IAA-stimulated sections are typically of an order of 3.5–4.0 mm over the 5-mm length at time zero.

* Present address: Department of Biochemistry and Biophysics, Iowa State University, Ames, Iowa.

Fig. 2. 80 S ribosomes and their rRNA for *Avena* coleoptile. A, A cytoplasmic extract of coleoptile homogenate (total volume: 2 ml. in 0.02 M *tris*, 0.02 M KCl, 10⁻² M MgCl₂, pH 7.8 at 5° C) was centrifuged at 15,000g for 10 min and made 0.5 per cent sodium deoxycholate. The clarified extract was then run on a 5–20 per cent w/v sucrose gradient (in the *tris* buffer) at 4° C for 4 h at 24,000 r.p.m. 1.0-ml. fractions were collected and their O.D.₂₆₀ determined. B, To show the presence of two sedimentation classes of rRNA in ribosomes thus isolated, fraction 10 (corresponding to 80 S ribosomes) was dialysed against 0.1 M NaCl, 0.005 M MgCl₂, 0.5 per cent SDS, pH 7.8 at 5° C. This was run at 24,000 r.p.m. on a 15–40 per cent w/v sucrose gradient containing NaCl, MgCl₂ and SDS in the concentrations listed. 1.0-ml. fractions were collected, and their O.D.₂₆₀ values determined.

for 2 h at –20° C, collected by centrifugation, and reprecipitated in cold ethanol overnight.

Coleoptile RNA thus obtained was dissolved in 1 ml. of the acetate buffer and layered on to a 20-ml. linear sucrose gradient (5–20 per cent w/v in the acetate buffer already described here). Following centrifugation at 4° C in the SW 25 rotor for 18 h at 24,000 r.p.m., 0.8 ml. fractions were collected in 1.0 ml. water. Aliquots of 0.5 ml. from each fraction were added to 15 ml. of Bray's solution⁷ and assayed for tritium in an Ansitron liquid scintillation counter (counting efficiency: 20 per cent with a background of 24 c.p.m.). The O.D.₂₆₀ values for the fraction volumes remaining were determined by use of a Beckman DU spectrophotometer.

Morphological response to IAA; effects of actinomycin D. In our experimental system, *Avena* coleoptile sections show a linear rate of increase in length during the first 3 or 10 h, and a substantially reduced rate thereafter to 24 h (insert, Fig. 1). This observation is in agreement with that of Shibaoka and Hurusawa⁸. Examining in detail the initial 8-h response for effects of IAA and actinomycin D (Fig. 1), we find the following: (1) a marked acceleration of rate of increase in length for IAA-stimulated sections over that of controls (ratio of rates: 2.6 as reported by Cleland⁹); (2) only light inhibition of either control or IAA responses in the presence of actinomycin D.

This initial lack of sensitivity to actinomycin D (cf. Fig. 1 and insert) may represent either a delay in time for coleoptile uptake of the inhibitor from the medium or that part of the coleoptile's morphological response is truly insensitive to actinomycin D. Supporting the latter possibility is our finding that increased concentrations of actinomycin D (100 µg/ml.) and/or pretreatment periods (30 min; 1 h) also result in the trends noted in Fig. 1 (see following). By 24 h the inhibitory effects of actinomycin

D on IAA and control responses of coleoptiles are clearly discernible.

Characterization of ribosomes and RNA. From 80 S ribosomes¹⁰ isolated from cytoplasmic extracts of coleoptile sections (Fig. 2), and from whole sections, RNA was phenol extracted and characterized on sucrose gradients as already described here (cf. Fig. 2 and Fig. 3A). By comparison with sedimentation profiles of RNA with known *s* values and by analyses in the Model E analytical ultracentrifuge, we determined the presence of 30 S and 20 S classes of rRNA in *Avena* coleoptile sections.

Base composition for total RNA of sections is as follows for percentages of the nucleoside monophosphates UMP, GMP, AMP and CMP; 13.6, 28.2, 23.4 and 24.8 (GC/AU = 1.70)¹¹. For rRNA extracted from 80 S cytoplasmic ribosomes, the values are: for 30 S fractions, 19.2, 32.9, 23.8 and 24.1 (1.33); for 20 S fractions, 18.9, 33.8, 23.1 and 24.2 (1.38)¹¹.

The higher GC/AU ratio of 1.70 for total RNA hints of a higher GC content for soluble RNA of coleoptiles. The base composition for total RNA of *Avena* coleoptile is close to that for tobacco leaf RNA, but its GC/AU is higher than that reported for four other plant species¹².

Stimulation of RNA synthesis by IAA; effects of actinomycin D. As shown in Figs. 3 and 4, the presence of IAA in culture medium results in a marked increase (about 50 per cent) in the incorporation of ³H-uridine into all classes of coleoptile RNA. Under the conditions here used, the extent of this stimulation is nearly the same (48, 60, 47 per cent) for three major classes (30 S, 20 S, 4 S) of RNA. The ranges of variation for triplicate experiments are shown in Fig. 4. Evidence for an effect of IAA on net synthesis of coleoptile RNA is presented in Table 1. In each case, the amount of O.D.₂₆₀-absorbing material extracted as RNA is greater from IAA-stimulated sections than from control sections.

Actinomycin D suppresses the incorporation of ³H-uridine into coleoptile rRNA (control) as well as inhibits the stimulation of such incorporation by IAA (cf. Fig. 5 with Fig. 3). The residual radioactivity remaining on sucrose gradients (Fig. 5) of RNA extracted from actino-

Fig. 3. Sucrose density gradient profiles showing effects of IAA on incorporation of ³H-uridine into RNA in *Avena* coleoptile sections. Closed (●) and open (○) circles denote values for O.D.₂₆₀ and radioactivity (c.p.m.).

Fig. 4. Specific activities of the labelled RNA extracted from control (shaded bars) and IAA-stimulated (open bars) *Avena* coleoptile sections. Values are derived from triplicate experiments (one of which is shown in Fig. 3), and are expressed for each class of RNA as well as for total RNA. The specific activity of each class is determined from the five fractions comprising each UV peak (the peak fraction plus the two on either side). The specific activity of total RNA is based on the total radioactivity and $O.D._{260}$ values for each gradient.

mycin *D*-treated sections demonstrates, however, two peaks. That the bulk of this residual radioactivity stems from RNA synthesis by actinomycin *D*-resistant bacteria or chloroplasts¹⁰ is evident from the slower rate of sedimentation; on the basis of comparison with $O.D._{260}$ -absorbing boundaries of 30 *S* and 20 *S* coleoptile *r*RNA, these peaks show smaller *S* values corresponding in the main to bacterial¹¹ or chloroplast *r*RNA^{10,12}.

Although the close coincidence of $O.D._{260}$ -absorbing and radioactivity profiles from control and IAA-stimulated systems (Fig. 3) indicated otherwise, we tested the possibility that enhanced incorporation of 3H -uridine into RNA extracted from coleoptiles is a result of influence of IAA on bacterial RNA synthesis. The results noted in Table 2 show this not to be the case; acid-insoluble radioactivity for equal volumes of culture medium containing coleoptile sections incubated for 8 h exhibits no difference for the presence or absence of IAA.

Our findings for *Avena* suggest that the role of indolyl-3-acetic acid as an inducer of plant growth is, in part at least, biochemically manifest by an increase in rate of synthesis of ribosomal and soluble RNA. The incorporation of 3H -uridine into each class of RNA is markedly stimulated in the presence of this naturally occurring hormone. Actinomycin *D* effectively suppresses RNA synthesis in both control and IAA-stimulated systems. This points strongly to the involvement of DNA-dependent RNA synthesis in the early action of the hormone, and we infer that IAA exerts its influence by indirectly or directly activating some unknown rate-limiting step in such RNA synthesis. We note, nevertheless, that inhibition by actinomycin *D* of hormone-stimulated RNA synthesis indicates only that the DNA-RNA complex of the genome must be functional at the time of hormone action. Suppression of hormone action by the inhibitor does not mean that the hormone acts at the site of the gene.

It should be noted that *Avena* coleoptile sections undergo: (1)

Table 1. PHENOL-EXTRACTED RNA FROM SUB-APICAL SECTIONS OF *Avena* COLEOPTILE

Exp.	Control	IAA
1	8.282	9.958
2	8.179	9.078
3	8.806	9.396
Average	8.422	9.477

The $O.D._{260}$ units extracted as RNA are expressed for each experiment as the mathematical summation of the thirty-six $O.D._{260}$ values for the fractions collected from sucrose gradients run under standard conditions (Fig. 3). Each experiment is for 200 control or 200 IAA-stimulated coleoptiles incubated for 8 h as described in the text.

Table 2. ACID-INSOLUBLE RADIOACTIVITY OF COLEOPTILE CULTURE MEDIUM

Exp.	Control	IAA
1	1,176,660 c.p.m.	1,032,900 c.p.m.
2	983,520	1,082,760
3	970,980	984,600
Average	1,043,720	1,033,420

From standard incubation medium (containing 200 coleoptiles, no penicillin, 0.002 mM 3H -uridine, and either no IAA or 1×10^{-4} M IAA) 1.0 ml. media samples were taken after 8 h incubation and assayed for acid-insoluble tritium as follows: 0.5 mg of carrier albumin was added, followed by 10 per cent trichloroacetic acid (TCA) to a final concentration of 5 per cent. The precipitates were collected on 'Millipore' filters, thoroughly washed with cold 5 per cent TCA, dried, and counted by liquid scintillation. Values are expressed for the total 10-ml. culture.

increases in length to some extent in the presence of actinomycin *D*; (2) increases to a greater extent in the presence of actinomycin *D* and IAA (Fig. 1). That this occurs concomitantly with inhibition of RNA synthesis (cf. Fig. 1 with Fig. 5) is further evidence for the possibility that part of the morphological response to control medium and to IAA is insensitive to actinomycin *D*.

A goal of many workers concerned with the roles of nucleic acid formation and function in early hormone action is to determine the degree of similarity or dissimilarity in the pattern of sequential biochemical responses of specific vertebrate, invertebrate, and plant tissues to their characteristic hormones¹³. For two vertebrate hormonal mechanisms (thyroxine \rightarrow rat liver¹⁴; oestrogen \rightarrow rat uterus¹⁵), it is now clear that stimulation of nuclear RNA synthesis precedes stimulation of two DNA-dependent RNA polymerase activities in early hormone action. Whether such sequences will hold true for invertebrate and plant hormonal mechanisms, as well as other vertebrate ones, remains to be determined. For hormone-sensitive plant tissues, however, an interesting set of questions arises concerning nuclear and/or (?) cytoplasmic sites of action and synthesis. There is now evidence¹⁴ for the presence of DNA and DNA-dependent RNA polymerase in chloroplasts—units functioning as 'cells within cells', thus providing extranuclear sites of RNA synthesis. Detailed time-sequence investigations of RNA synthesis and RNA polymerase activities for nuclear, chloroplast and microsomal fractions isolated from *Avena* coleoptile sections cultured in the presence or absence of IAA may provide the answers.

Fig. 5. Sucrose density gradient profiles showing effects of actinomycin *D* in the absence (A) or presence (B) of IAA on incorporation of 3H -uridine into RNA in *Avena* coleoptile sections. Closed (●) and open (○) circles denote $O.D._{260}$ and radioactivity (c.p.m.) values for fractions.

PRINCIPLES OF CELL MOTILITY: THE DIRECTION OF CELL MOVEMENT AND CANCER INVASION

By DR. S. B. CARTER

Imperial Chemical Industries Limited, Pharmaceuticals Division, Alderley Park, Macclesfield, Cheshire

INVESTIGATIONS of cell motility are generally carried out with cells attached to glass surfaces, and, in many cases, the influence which the glass itself may have on patterns of cell movement and behaviour is not fully taken into account. The use of unconventional transparent materials serves to emphasize the importance of the part played by the substrate in cell motility. Cellulose acetate has been selected from a wide range of available materials as being of particular value in experiments of this type.

Mammalian cells in culture do not readily adhere to a surface of cellulose acetate, but if this surface is metallized *in vacuo*, cultured cells will adhere to it and spread. By varying the amount of metal deposited it is possible to produce a range of surfaces allowing different degrees of cell adhesion.

The investigation of cell behaviour on various surfaces prepared in this way has led me to draw a number of general conclusions about the principles which govern the direction of cell movement, and the mechanism of cell motility itself.

In all the experiments to be described the cells used were mouse fibroblasts (Earle's L strain), and these were cultured in Eagle's medium¹, with 8 per cent calf serum. A culture chamber of new design was used and this will be described elsewhere. Cover glasses may be coated with an acetate film by immersing them in a 0.5 per cent solution of cellulose acetate (acetyl value 54-56 per cent) in 1,4-dioxan. These are drained in an atmosphere

saturated with dioxan, and dried under vacuum to avoid clouding by atmospheric humidity. The dried films are then heated to 280°C for 10 sec, a procedure which melts the acetate layer, fixing it firmly to the glass and sterilizing it at the same time. The surface of the film must be protected from physical and chemical contamination. Purity of materials is essential.

Metallic palladium is deposited on the acetate surface in a vacuum coating unit of the type used for shadow casting in electron microscopy. A measured length of fine palladium wire is placed on a cleaned molybdenum strip and heated to white heat at 10⁻⁴ mm mercury. The vaporized palladium is deposited on the acetate film by placing the cover glass above the molybdenum strip at a height which can be varied to control the amount of metal deposited. The minimum quantity of palladium necessary to allow full cell adherence to the film gives a very fine deposit which cannot be detected by eye. Several other metals have been found to be equally effective in this respect, but palladium has proved to be the most convenient and there have been no indications of it being responsible for any toxicity.

In order to make a gradient of metal deposition and therefore a surface offering progressively increasing cell adhesion, a number of techniques have been used. The simplest of these is to place a short length of stainless steel rod, 0.5 mm in diameter, in contact with the acetate film. The film is then shadowed by vaporizing 2 mg of fine palladium wire, rolled into a small pellet, at a distance

of 10 cm. This makes a relatively heavy deposition of metal which clearly outlines the intervening rod. Owing to the scattering of metal particles, however, a much finer deposit of palladium extends beyond the visibly shadowed area, and tapers off in the narrowing angle under the curved surface of the rod. A gradient of metal deposition is therefore produced. The advantage of this method is that the upper limit of the gradient is clearly defined by the visible edge of the densely shadowed area.

Cell Movement on a Gradient of Adhesion

Fig. 1 shows a number of cells photographed shortly after attachment, lying on an adhesion gradient prepared in this way. The full metal deposit is visible as a darker area in the upper part of the photograph, and the gradient extends from the bottom of the photograph to the edge of this darker area. Fig. 2 shows the same field after an interval of 8 h, and Fig. 3 shows the tracks of all cells during this period, plotted from a series of intermediate photographs.

It will be seen that the cells on the gradient move in the direction of increasing adhesion to the substrate, and their uniformity of movement contrasts with the apparently random movement of cells on the evenly metallized cellulose acetate, or on glass. As the cells crowd together at the upper end of the gradient, progressively increasing cell-to-cell contacts interfere with the movement of individual cells. Nevertheless the cell migration continues in the same direction, and Fig. 4 shows the same field again after 48 h. At this stage the free edge of the cell sheet is retracting, whereas under more usual conditions a free edge of this type would advance.

Not only is cell movement on the gradient directional, but also the cell tracks are longer and indicate more efficient motility. This is particularly evident in less-crowded cultures where there is more room for individual cell movement, and in a number of experiments of this

Fig. 1. Newly attached cells on an adhesion gradient. Substrate adhesion increases from the bottom of the photograph to the edge of the darker area. ($\times 125$). (All photomicrographs in this article were taken by phase contrast illumination.)

Fig. 2. The same field as Fig. 1 after an interval of 8 h. The cells have moved up the adhesion gradient towards the darker area at the top. ($\times 125$)

Fig. 3. The movement of individual cells on an adhesion gradient. The circles represent the original positions of the cell nuclei in Fig. 1, and the lines trace the paths followed by these nuclei to their positions in Fig. 2 8 h later. The two nuclei marked with crosses represent cells which became detached. ($\times 125$)

Fig. 4. The same field as in Fig. 1 after 48 h. The cells have continued to move up the adhesion gradient in spite of the crowding which results. The two isolated cells are late-comers which were outside the original field shown in Fig. 1. ($\times 125$)

type the average length of cell track on the gradient was four to five times as long as that on the evenly metallized surface. The speed of cell movement on the evenly metallized surface is of the same order as it is on glass under similar conditions.

It seems probable that movement towards surfaces offering greater adhesion is a general phenomenon applicable to all metazoan cells which are dependent on contact with a surface for their motility, and I believe that this is the essential principle which directs and controls all cell movements of this type. It is generally appreciated that cell motility and cell adhesion are interrelated, but the directness and simplicity of this relationship have not previously been demonstrated by experiment.

Gustafson and Wolpert² suggested on theoretical grounds that cells would tend to move up a gradient of increasing substrate adhesion, but the mechanism they proposed, involving competition between randomly extended pseudopodia, would not predict the immediately directional movement of individual cells which in fact occurs. I suggest that this phenomenon should be called 'haptotaxis' (Greek: haptin, to fasten; taxis, arrangement), conveying the idea that the movement of a cell is controlled by the relative strengths of its peripheral adhesions, and that movements directed in this way, together with the influence of patterns of adhesion on cell shape, are responsible for the arrangement of cells into complex and ordered tissues.

On this basis, the cell migrations involved in morphogenesis, inflammation, wound healing, tumour invasion and indeed all tissue cell movements, are considered to be the result of haptotactic responses by the cells involved, and correspondingly the relative stability of cells in differentiated adult tissues is due essentially to the lack of adhesion differentials on which effective cell movement depends. In discussing the possible mechanisms which

might control cell movement, Weiss³ pointed out that any such mechanism must involve selective conduction or selective fixation. His third principle of selective elimination is not strictly concerned with cell motility. It is interesting to note that the idea of haptotaxis effectively combines both these principles of cell movement.

Contact Inhibition

The concept of contact inhibition⁴ is valuable in providing a primary explanation for the differences in behaviour between normal and malignant cells. Cells which inhibit movement in each other on contact, and therefore tend to form monolayers in culture, are said to show contact inhibition; whereas those which move over each other and pile up into multiple layers are said to show loss of contact inhibition. To a limited extent this distinction divides normal from malignant cells, and a change in the pattern of cell growth towards loss of contact inhibition serves to indicate the transformation of cells, for example by oncogenic viruses.

However, by varying the amount of palladium deposited on a cellulose acetate film and producing surfaces which allow different degrees of cell adhesion, it is possible to change completely the pattern of growth of the same type of cell, without otherwise altering the cultural conditions.

The cells in Fig. 5 are arranged in a monolayer and are demonstrating contact inhibition. These cells are attached to a cover glass which has been coated with acetate and exposed to vaporized palladium. Fig. 6 shows cells from the same culture as they appear on a different part of the cover glass where it has been masked to reduce the amount of palladium deposited. Here the cells are clumped together and would be said to demonstrate loss of contact inhibition. An intermediate stage in which cells show a tendency to monolayer, but with many cells overlapping, can be found in a narrow region between the two areas showing these strikingly different patterns of growth. This finding indicates that contact inhibition, or lack of it, cannot be regarded as an attribute of the cell itself, but describes its relationship to other cells in the presence of a particular alternative substrate.

The phenomenon of contact inhibition can be explained on the basis of haptotactic movement. Cells showing contact inhibition on glass are demonstrating that they can adhere more strongly to this material than they can to each other. Cell movement will therefore be towards any free glass surface so that the monolayer is preserved. Cells showing loss of contact inhibition on glass can adhere more strongly to each other, and will tend to leave the glass surface and pile up in multiple layers. This type of explanation is similar to one of several possibilities considered by Abercrombie and Ambrose⁵, but Abercrombie⁶ has since suggested that the explanation least open to

Fig. 5. 'L' cells showing contact inhibition on metallized cellulose acetate. ($\times 325$)

Fig. 6. 'L' cells showing loss of contact inhibition on very lightly metallized cellulose acetate. These cells were growing on a different area of the same cover glass as those shown in Fig. 5. ($\times 325$)

objection is that adhesion between cells inhibits the ruffled membrane, as argued by Curtis^{7,8}. In putting the opposite case it should be made clear that it is a relative lack of adhesion to the new substrate which is suggested as the operative mechanism, and this need not mean a low degree of adhesion in absolute terms. It is also important to emphasize that in discussing the adhesion of cells as it affects their motile behaviour, I am referring to the adhesion which occurs immediately on contact. The adhesion between cells which may develop on more prolonged contact is not at present being considered. The argument used by Abercrombie⁹ against this type of explanation for contact inhibition is that it fails to account for the paralysis of the ruffling movements of the cell. In a later paper concerned with the mechanism of cell motility, I hope to show that this objection can be overcome.

The arbitrary choice of glass as the surface on which most cells in culture are investigated makes the description of a cell in terms of contact inhibition equally arbitrary, though under standardized conditions not without practical value. Unfortunately glass exists in many forms, and its surface properties are readily changed by washing procedures and by substances in the culture medium itself.

Contact Guidance

The principle of contact guidance, elaborated by Weiss¹⁰, can also be explained on the basis of cell movement along a path of preferential adhesion. Although this mechanism is to a large extent implied by Weiss, he argues against the acceptance of any simple explanation in these terms. Orientated structures are likely to present a correspondingly orientated pattern of differing adhesion. This may be so even if the components in the orientated structure are all of the same material, since curvatures of the surface will affect the relative densities of the surface elements which may be concerned with adhesion.

Very precise contact guidance can be achieved by cutting narrow channels in a thin film of cellulose acetate so that the underlying glass is exposed, thereby providing a path offering far greater adherence for cells than the surrounding acetate (Fig. 7). Weiss has suggested that the mechanism of contact guidance may involve micro-orientation of the guiding surface, and has considered how this orientation could be transferred to the molecules of the cell surface in contact with it, and hence to the cell as a whole. It seems unlikely that there should be an appropriately orientated microstructure on a glass surface which has been exposed by removing a narrow strip of cellulose acetate, although such a microstructure could conceivably be imposed by the cutting instrument used to remove it.

Fig. 7. Contact guidance along a channel cut through a film of cellulose acetate on glass. ($\times 225$)

Contact guidance can also be demonstrated on cellulose acetate when the path of preferential adhesion is made by overlaying with vaporized palladium rather than cutting down to underlying glass.

Such a path can be made by masking the acetate surface and restricting the deposition of metal to a strip of any desired width. Fig. 8 shows cells demonstrating contact guidance along a path made in this way. There is no reason why a metallized strip should have an orientated microstructure, and the simple interpretation involving differential adhesion alone seems adequate as a primary explanation for contact guidance phenomena.

Chemotaxis

There are probably many thousands of substances which can evoke chemotactic responses *in vivo*, but the number which demonstrate this effect under strictly *in vitro* conditions is remarkably small¹¹. The explanation for this may be that the chemotactic substance is acting indirectly by damaging or otherwise altering the surfaces of cells and non-cellular structures in its neighbourhood. This surface change enables the normally non-adherent leucocyte, for example, to adhere. Since the surface change will be greatest in closest proximity to the chemotactic agent, a gradient of surface adhesiveness will be formed to guide the leucocyte to the appropriate area. Such a gradient may be reinforced by the action of substances released by the damaged cells, and it is probable that these substances rather than the chemotactic agent itself are mainly responsible for the adhesion gradient produced. Chemotaxis is difficult to demonstrate *in vitro* because artificial substrates are less susceptible to these surface changes. A direct effect on the leucocyte is also possible since the leucocyte itself could suffer surface changes which would make it more adhesive on the side nearest to the chemotactic stimulus. Failure to demonstrate *in vitro* responses to the majority of agents which are chemotactic *in vivo* suggests that this direct effect may be relatively unimportant. The suggestion that chemotaxis is a special case of haptotaxis applies equally well to negative chemotaxis, but in applying this principle there is no need to consider it in negative terms.

Cancer Invasion

If malignant invasion is due to the operation of haptotaxis, the implication would be that cancer cells can form stronger adhesions to surrounding normal cells than they can to each other.

It was originally shown by Coman¹² that cancer cells have a reduced mutual adhesiveness, and it has also been found that the net negative charge on the surface of a virus-transformed cell is higher than the surface charge on a homologous normal cell¹³. It seems likely that these two findings are closely related, and on theoretical grounds

it might be expected that a cancer cell would adhere more firmly to a normal cell than to another cancer cell because the repulsion due to the combined surface charges would be less.

To obtain absolute measurements of the adhesion between two cells of individually known type would be difficult, but if haptotaxis is accepted as a principle of cell movement, then the direction of cell movement itself can be used to give an indication of the relative adhesiveness of two surfaces for a particular cell.

Abercrombie, Heaysman and Karthaus¹⁴ made the important observation that confronted outgrowths from mouse sarcoma and chick embryo tissue showed more cell overlaps than occurred in a corresponding experiment with two cultures of chick tissue. This involves a comparison of normal and malignant cells from unrelated species, and the experiment is further complicated by the presence of a third surface in the form of a plasma coagulum. Although it points in the right direction, an experiment of this complexity would be difficult to interpret with confidence in terms of relative surface adhesion.

The value of virus transformation in culture is that it makes possible the comparison of normal cells with cells which are as nearly as possible their malignant counterparts. Vogt and Rubin¹⁵ observed that chick fibroblasts transformed by Rous sarcoma virus form multi-layered clumps on glass, but migrate readily over the sheet of untransformed cells. This suggests that the transformed cells are more adherent to themselves than to glass and more adherent to corresponding normal cells than to each other. Even so, it would simplify the interpretation of this experiment to eliminate any possible interference by the glass so that the comparison can be restricted to the cell surfaces only. For this reason some interesting experiments by Stoker¹⁶ are particularly relevant. He showed that whereas hamster cells transformed by polyoma virus formed distinct heaped-up colonies on glass, these same cells did not produce colonies when seeded onto pre-existing monolayers of normal hamster cells. Although he found evidence that the rate of division of the transformed cells was reduced under these conditions, their failure to form multi-layered colonies could also indicate that they were spreading over the pre-existing monolayer and, therefore, demonstrating a stronger attachment to normal cells than to each other. Stoker's experiments were not, of course, designed to test this hypothesis, and his own interpretation involves an entirely different theory in relation to the mechanism of contact inhibition. Nevertheless, this type of experiment closely parallels the experiment previously described in which cells were shown to clump or spread out according to the adhesiveness of the underlying surface.

Although these experiments with transformed cells point to the conclusion that malignant cells can adhere more strongly to their normal counterparts than to each

Fig. 8. Contact guidance on a cellulose acetate film coated in a narrow strip with evaporated palladium. ($\times 225$)

other, it is clear that further experiments are required, and these need to be specifically designed to make interpretation in these terms as direct as possible. In addition, it is necessary to establish haptotaxis more firmly as the overriding principle of cell movement. In order to do this it is essential to relate it to the underlying mechanism of cell motility, and this will be attempted in a subsequent paper.

On the basis of haptotactic cell movements, many aspects of the natural history of malignant disease can be interpreted. In local invasion, the peripheral tumour cells move away from the tumour mass into the surrounding tissue in response to the adhesion differential, and are followed immediately by other cells moving under the same influence. In this way, a column of cells tends to be formed and the process of malignant invasion becomes more consistent in direction and consequently more efficient than if individual cells were cut off from the tumour mass so that they were no longer subject to the directional cue provided by the presence of normal cells in front and malignant cells behind.

The pattern of invasion is affected by tissue architecture, not simply on the basis of the physical structures encountered, but also in accordance with the degree of adherence that the cellular and non-cellular components of the structure offer to the invading cells. Similarly the pattern of metastasis for a particular type of tumour is partly determined by anatomical considerations, and partly by the adhesiveness of the endothelial cells lining blood vessels and lymphatics in different tissues for the particular type of malignant cell. The surface properties of these endothelial cells would be expected to vary according to the differing physiological environments to which they are subjected in different types of tissue.

The invasiveness of a particular tumour cannot be regarded as a characteristic solely of the tumour itself, since the nature of the surrounding normal cells plays a part in determining the degree to which tumour to normal cell adhesion exceeds mutual tumour cell adhesion. For this reason, a tumour metastasis in a different tissue may show a greater or a lesser degree of invasiveness in its new

site when compared with the primary tumour, and it would be predicted that some tumours which are non-invasive and regarded as 'benign' in their primary sites could become 'malignant' if artificially transferred elsewhere.

It is important to bear in mind that the cells involved in malignant invasion are not moving in a stationary field. All tissue cells are potentially motile, and normal cells may move in relation to malignant cells for precisely the same reasons as malignant cells move in relation to normal cells. The movement of fibrocytes, for example, in contact with some types of neoplastic cells can result in the effective walling off and containment of a tumour within a fibrous capsule, and the penetration of fibrocytes into the substance of a carcinoma can convert it into a scirrhous type of tumour. The infiltration of some tumours by lymphocytes is also a clear case of the 'invasion' of cancerous tissue by normal cells. It may be more rewarding to consider such phenomena with reference to a defined concept such as haptotaxis than to describe them in non-committal terms of 'reaction' to the tumour. Only a brief indication of the application of such a concept has been attempted here.

I thank Miss Janet Way for technical assistance.

A SEX-DEPENDENT FACTOR IN APLASTIC ANAEMIA?

By DR D. E. PEGG and J. E. BURNS

Departments of Radiotherapy and Physics, Westminster Hospital, London, S.W.1

APLASTIC anaemia is characterized by the deficient production of peripheral blood cells and is nearly always attended, and presumably caused, by severe bone marrow hypoplasia. The fundamental cause of the condition is usually unknown, and although spontaneous remissions do occur, they are not common, and treatment has usually been conspicuously unsuccessful. Animal experiments in bone marrow transplantation indicated a possible new approach to the management of this disease by the grafting of healthy bone marrow cells: allogeneic marrow infusions are attended by difficulties and hazards which are avoided by the use of syngeneic donors, and on the rare occasions when a patient with aplastic anaemia has a normal identical twin it is possible to duplicate this favourable circumstance clinically. Seven such cases have been reported (Table 1).

In three of the four successful cases recovery was rapid and complete (Cases 2, 4 and 5), while in the fourth (Case 6) the response was slow and incomplete following the first marrow infusion, but a second infusion was more satisfactory although some thrombocytopenia persists*. Of the unsuccessful cases, the first (Case 1) has since undergone a slow and partial recovery while under treatment with steroids and testosterone (severe thrombocytopenia persists)*, Case 3 was not significantly benefited, and Case 7 died one month later. In each of the

four successful cases the author of the report was convinced that the treatment had been responsible. It is of course necessary to consider the possibility that the recoveries were spontaneous and coincided with the treatment purely by chance. This seems highly improbable: the spontaneous recovery rate is low, particularly when the disease has been present for a considerable time, as it had in Cases 4, 5 and 6 particularly. If it is accepted that the treatment was responsible for the recovery of the four successful cases, some attempt must be made to account for its failure in the other three. There appears to be no correlation between the result of the treatment and the cause of the aplasia (in so far as it is known), the age of the subject, or the amount of marrow injected: it is striking, however, that all the female cases recovered whereas all the male cases did not. To calculate the probability of this result occurring purely by chance, where the true reason is the operation of a factor not dependent on sex, it is necessary to make some assumption concerning the number of cases expected to recover. Table 2 shows the calculated probability for a selection of overall success rates. The highest probability is given by assuming that four recoveries will occur in any seven cases treated (the observed success rate) and on this assumption the probability of the observed distribution of successes and failures between males and females

Table 1

Case No.	Age and sex	Aetiology	Duration of aplasia	Amount of marrow	Result	Ref.
1	3 M	Chloramphenicol and/or sulphonamides probably	4 months to first treatment	3.6×10^9 cells	Unsuccessful	1
2	7 F	Paramethadione	6 months to second treatment	2.8×10^9 cells	Complete recovery	2
3	54 M	Unknown	3 weeks	5.6×10^9 cells	Unsuccessful	3
			Unknown, but longer than 2 months	4.8×10^9 cells		
4	9 F	Unknown	2.5 years	7.3×10^9 cells	Complete recovery	4
5	9 F	Unknown	7 months	6.1×10^9 cells	Complete recovery	5
6	55 F	Chloramphenicol	10 months to first treatment	6.0×10^9 cells	Recovery with some persistent thrombocytopenia	6
			3 years to second treatment			
7	15 M	Unknown	1 month	2.0×10^9 cells	Unsuccessful	7

Table 2. PROBABILITY THAT FOUR FEMALE CASES SHOULD ALL SUCCEED AND THREE MALE CASES SHOULD ALL FAIL FOR VARIOUS POSTULATED SUCCESS RATES

Success rate (%)	Probability
90	0.000656 or 1 in 1,520
80	0.00328 or 1 in 305
70	0.00848 or 1 in 154
60	0.00829 or 1 in 121
50	0.00781 or 1 in 128
40	0.00553 or 1 in 181
30	0.00278 or 1 in 366
20	0.000819 or 1 in 1,220
10	0.0000729 or 1 in 13,700

occurring purely by chance can be shown to be 0.0084 or 1 in 119, a rather unlikely (but not impossible) chance. It is, at any rate, sufficient to suggest quite strongly that a sex-determined factor is involved in the treatment of aplastic anaemia by syngeneic marrow infusion.

There appear to be two possible explanations for this quite unexpected observation: either a sex-determined factor is involved in the disease itself and the female disease is actually different from the male disease, or a sex-linked factor determines the success of the treatment. These possibilities will be considered in turn.

(A) *The disease.* Aplastic anaemia appears to affect both sexes equally¹⁰ although cases have been described in which there has been good evidence that sex or hormonal factors have played a crucial part. Havard and Scott themselves described two patients in whom the onset of aplasia was associated with pregnancy and one of these patients relapsed with each of her three pregnancies and remained in remission following her last pregnancy. Similar occurrences have been noted by Lachmann *et al.*¹¹ Shahidi and Diamond¹² reported two cases of aplastic anaemia in male children in which spontaneous remissions occurred precisely at the time of the onset of puberty. It is, in fact, well known that the sex hormones play an important part in the control of haemopoiesis; Gordon and Charipper¹³ showed that the difference in mean haemoglobin levels of male and female rats is due to the action of the sex hormones. The administration of large doses of testosterone in carcinoma of the breast often produces erythroid hyperplasia and even mild polycythaemia¹⁴ and similar therapy has since been advocated for the treatment of juvenile aplastic anaemia¹⁵ and myeloid metaplasia¹⁶. In addition, there is clear evidence that sex-linked genetic factors are involved in haemopoiesis. Rundles and Falls¹⁷ have described a form of sideroblastic anaemia which is hereditary and almost certainly sex-linked, since it affected only males and was recessive in females: the congenital pancytopenia of Fanconi is more common in males than females.

It is quite clear that this evidence falls a long way short of establishing the existence of two, sex-linked forms of aplastic anaemia, and in the present state of knowledge it seems unlikely that this could explain the results of syngeneic marrow infusion.

(B) *The treatment.* It has of course been widely assumed that syngeneic marrow infusion would work, if at all, by cellular transplantation, but it has not perhaps been so readily appreciated that this also involves the assumption that the cause of aplastic anaemia is a primary failure of stem cell activity, presumably brought about by the action of a transient agent which leaves the stem cells

irreparably damaged but the marrow environment intact to accept a syngeneic graft. In fact there is overwhelming evidence against this. In the first place it is very difficult to conceive of an agent producing a specific totally lethal effect on one group of cells in a complex biological system (if it were not totally lethal, then spontaneous recovery would occur). In any event, since the leucocyte, platelet and reticulocyte counts never reach zero, there must be some intact stem cells remaining, and if this is so, and the marrow environment is intact, they would be expected to repopulate the marrow without further intervention their total number would certainly exceed 0.1 per cent of the normal total marrow cellularity, and this amount is adequate to repopulate the marrow spaces of lethally irradiated mice. There is therefore every reason to suppose that aplastic anaemia is not due to stem failure *per se*, but is due to an abnormality of the *milieu intérieur* either the absence of an essential metabolite or hormone or the presence of a specific depressor substance. If a depressor substance was responsible one would expect it also to affect the infused marrow, and prevent grafting. One is led to the conclusion that when syngeneic bone marrow is infused in aplastic anaemia, it does not act by haemopoietic cell transplantation as this is usually understood, but by a quite unknown stimulatory mechanism.

This conclusion is certainly surprising, and in view of the nature of the evidence on which it is based, it must be regarded as highly tentative. But in a disease where so little is understood it is perhaps justifiable to consider any reasonable hypothesis in the hope that it may lead by further observation and experiment to a greater understanding of the disease, and to more effective treatment. In particular it will be most interesting to see further attempts to treat aplastic anaemia with syngeneic bone marrow conform to the same pattern. Limited enquiries have brought to light only one additional case¹ This concerns a female aged twenty-three, who died 3 days after receiving 1.17×10^9 marrow cells from her twin; this is certainly too short a survival to permit an conclusion concerning the effectiveness of the marrow infusion.

LETTERS TO THE EDITOR

RADIO ASTRONOMY

Radio Structure of the Galactic Centre Region

RADIO observations have shown that the galactic centre region consists of a number of discrete sources. The brightest of these, Sagittarius A, is believed to represent the galactic nucleus. This communication describes a new series of observations of the region, made at frequencies of 8.25 and 15.50 Gc/s with a pencil-beam antenna. The angular resolutions were respectively 4.2 and 2.2 arc min, the latter being the highest pencil-beam resolution so far applied to the galactic centre region. The observations confirm that the microwave spectrum of Sagittarius A is non-thermal¹, show that the angular diameter of the source is approximately 3.5 arc min, and demonstrate that, adjacent to Sagittarius A, there is an irregular emission region, which is apparently thermal in nature. The relation between radio data concerning the galactic centre and optical information about the centres of nearby normal galaxies is also examined.

The observations were made with the 120-ft. paraboloid antenna at the Haystack field station of Massachusetts Institute of Technology, Lincoln Laboratory. The antenna has a Cassegrain feed system². The receiver at 8.25 Gc/s had a band-width of 0.5 Gc/s, and with an output time constant of 1 sec the minimum detectable signal was of the order of 0.1° K. The receiver at 15.50 Gc/s used two channels centred at 15.25 and 15.75 Gc/s, each having a band-width of 0.5 Gc/s. With an output time constant of 1 sec the minimum detectable signal for this receiver was 0.2° K. The outputs from the receivers were recorded by both analogue and digital equipment. The observations were made by taking drift-scans, at spacings of 2 arc

min in declination at 8.25 Gc/s, and at 1 arc min at 15.50 Gc/s. This procedure minimizes the effects of ground radiation scattered or diffracted into the antenna. The scans were taken when the galactic centre region was at meridian transit $\pm 2^\circ$, over which period its elevation ranged from 18 to 13 arc deg above the horizon.

Fig. 1a shows the radio brightness contours of the galactic centre region at 8.25 Gc/s and Fig. 1b shows the contours at 15.50 Gc/s. The bright source is Sagittarius A. To the north of Sagittarius A, and partially overlapping it, there is a complex emission region, which consists of an irregular curved ridge. This region may also be distinguished on contour maps at other frequencies^{3,4}. Beneath these sources, there is a well-known emission region extending over several arc degrees, which is not indicated in the diagrams.

Table 1. FLUX DENSITIES, ANGULAR DIAMETERS, AND POSITIONS OF RADIO SOURCES IN GALACTIC CENTRE REGION

	Sgr. A	Sgr. B1	Sgr. B2
Flux density ($\times 10^{-26}$ M.K.S.)			
at 8.25 Gc/s	150	35	125
at 15.50 Gc/s	100	60	190
Angular diameter (arc min)	4.0×2.5	7×5	17×5
Position (1950.0)			
right ascension	17h 42m 27s	17h 42m 34s	17h 42m 59s
declination	$-28^\circ 58' 5''$	$-28^\circ 51' 0''$	$-28^\circ 47' 0''$

Estimates of the flux densities of Sagittarius A at 8.25 and 15.50 Gc/s are given in Table 1. These values were derived on the assumption that the flux density of M87 was 47×10^{-26} M.K.S. units at 8.25 Gc/s and 28×10^{-26} units at 15.50 Gc/s. Beam-width corrections were made for both Sagittarius A and M87. The flux values for Sagittarius A fit closely on the intensity spectral curve of index $\alpha = -0.7$ given earlier by Maxwell and Downes¹, confirming the non-thermal character of the source. The position co-ordinates of Sagittarius A given in Table 1 are mean

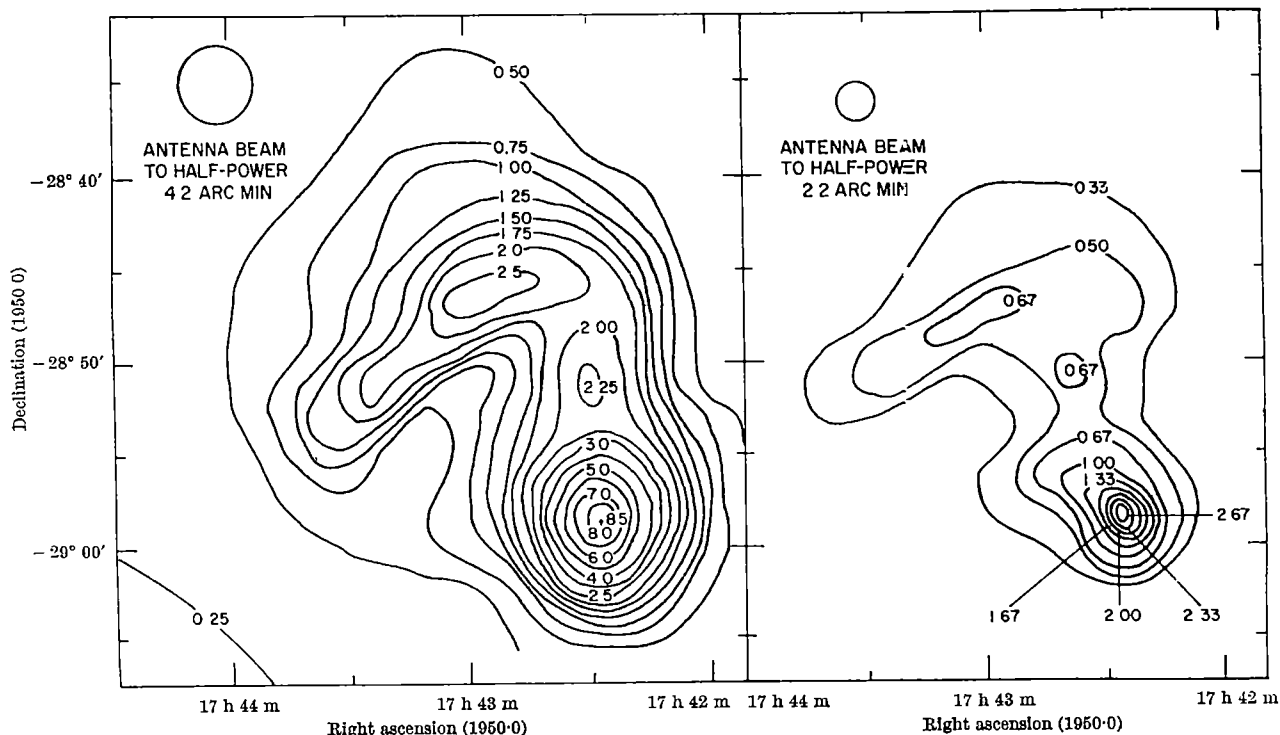

Fig. 1. a (Left), galactic centre region at 8.25 Gc/s. Contours represent antenna temperature in ° K, corrected by 4 per cent for extinction. b (Right), galactic centre region at 15.50 Gc/s. Contours represent antenna temperature in ° K, corrected by 8 per cent for extinction.

values taken from earlier position measurements of Maxwell and Downes, Hollinger³ and Broten *et al.*⁴.

To estimate flux densities from the irregular emission region north of Sagittarius A, we have divided it into two main areas, which we shall refer to as Sagittarius B1 and B2. The centres and angular diameters of these areas are listed in Table 1, the centres having been measured relative to the position of Sagittarius A. On Fig. 1b the centres are represented by the closed contours of antenna temperature 0.67° K. Integrated flux densities for Sagittarius B1 and B2 are given in Table 1. These values, however, should be regarded with caution, particularly at 15.50 Gc/s, since the present survey provides only a few brightness contours for the areas. Comparison of the integrated fluxes from these areas with data taken by Broten *et al.* at 5 Gc/s suggests that the sources are both thermal in nature and that they may therefore be H II regions. There is, however, no evidence to indicate that the sources are physically associated with Sagittarius A.

In considering the structure of the centre of our own galaxy, it is instructive to compare the existing radio data with optical data concerning the centres of two nearby normal galaxies, M31 and M51. (There is, of course, little optical evidence concerning the structure or nature of the centre of our own galaxy, since the centre is heavily obscured by intervening dust clouds.) Both M31 and M51 are observed optically to have a central nucleus of linear dimensions about 20 parsec^{5,6}. In each case this nucleus is embedded in a larger nuclear bulge of dimensions about 1,000 parsec. In the case of our own galaxy, if we believe Sagittarius A to be at the galactic centre and at a distance of 10 kiloparsec⁷, then its angular width of 3.5 arc min to half power would correspond to linear dimensions of the order of 10 parsec, which is comparable with the optical dimensions of the nuclei of the nearby normal galaxies. Similarly, if the extended source underlying Sagittarius A is regarded as radio evidence for a nuclear bulge at the centre of our own galaxy, the radio diameter of about 120 arc min¹ would correspond to linear dimensions of the order of 350 parsec.

Observations of the galactic centre by radio astronomers have now extended over some fifteen years, during which time angular discrimination has increased by a factor of about 30. With each improvement in resolution the central region has generally shown increasing structural complexity. Commencing in 1967, the region will be subject to a series of lunar occultations, and at that time we may look forward to a dramatic increase in the available angular resolution, perhaps by a factor of 100 or more. The detailed structure of this region should then be revealed much more fully.

We thank Mr. A. B. Hull and Dr. S. Weinreb of Lincoln Laboratory, and Mr. R. Rinehart and Mr. J. H. Taylor of Harvard University, for their assistance in making the observations. Lincoln Laboratory is a centre for research and development operated by the Massachusetts Institute of Technology with the support of the U.S. Air Force. The Harvard University part of the programme was supported by the U.S. National Science Foundation.

ASTROPHYSICS

Common Features of the Optical Continua associated with Violent Cosmic Events

THE purpose of this communication is to point out a similarity in the optical continua of several objects, all associated with violent events, but which otherwise have a diverse character. The objects are the nucleus of the Seyfert Galaxy NGC 4151, the galactic, nova-like object η Carinae, the Crab Nebula and the quasi-stellar radio source, 3C48. (The term nova-like is to some extent descriptive of the spectrum. In using it, we do not mean to imply a mechanism for the outburst in η Carinae. This outburst has involved energies characteristic of supernovae and, unlike either supernovae or novae, has a time scale of the order of a century.) The optical spectrum of NGC 4151 has been discussed by Seyfert¹ and Woltjer², that of η Carinae by Thackeray³, that of the Crab Nebula by Woltjer⁴ and Mayall⁵, and that of 3C48 by Greenstein and Schmidt⁶. The emission lines in all of these spectra show, as a common feature, evidence of internal motions as large as a few thousand km/sec. We indicate in Table 1 some of the principal observed features of these objects.

In independent investigations, we have recently found that NGC 4151 and η Carinae radiate continua that are remarkably similar to one another and to that observed in the Crab Nebula. Further, there are considerable grounds for believing that the optical continua of some of the quasi-stellar sources, such as 3C48, are of similar form. The continua are illustrated in Fig. 1, where we plot the logarithm of the flux per unit frequency interval, $\log F(\nu)$ (with an arbitrary vertical shift for each object), against the reciprocal wave-length (μ)⁻¹.

The observations of η Carinae were obtained with the photoelectric scanner at the Mount Stromlo Observatory. They will be discussed in conjunction with the results of coudé spectroscopy in a forthcoming paper by Rodgers and Searle. For our purpose it is important to note that there is no observable stellar component in the spectrum of η Carinae. Although the spectrum of η Carinae is crowded with emission lines, notably of [Fe II], a smooth, featureless continuum is clearly present and the coudé spectrograms have been used to correct the scan data in order to obtain the curve shown in Fig. 1. η Carinae lies in the galactic plane and suffers considerable interstellar extinction. To obtain the results given in Fig. 1, a large but well-determined correction for this has been applied to the observed fluxes.

The scans of NGC 4151 were obtained by Oke using the 200-in. telescope at Palomar Mountain and the 100-in. telescope at Mount Wilson. They will be discussed, together with photographic spectra obtained by Sargent at Mount Wilson, in a forthcoming paper. The nucleus of NGC 4151 has a continuous spectrum on which are superimposed emission lines; there is no sign in the spectrum of this object of a stellar absorption component such as is found in some of the other Seyfert nuclei, for example, NGC 1068. The continuum shown in Fig. 1 for NGC 4151 has been corrected for the effect of emission lines, but no correction for interstellar reddening has been necessary in this case.

The optical continuous energy distribution of the Crab Nebula has been measured by O'Dell⁷ using narrow band observations over the wave-length range 3210–8440 Å. Estimates of interstellar reddening were made through

Table 1. RADIO AND OPTICAL PARAMETERS

Object	Distance (pc)	Radius (cm)	Luminosity at 45560 (ergs/sec/Å)	Ratio of radio to optical luminosity $F(\nu = 10^9 \text{ epc})$ $F(\nu = 10^{15} \text{ epc})$	Equivalent width of $H\beta(\text{\AA})$
<i>NGC 4151</i>	10^7	1.5×10^{20}	7.8×10^{36}	< 0.1	140
η Car	1.5×10^3	6×10^{16}	2.3×10^{35}	< 0.3	114
Crab Nebula	1.1×10^3	9×10^{17}	1.8×10^{32}	10^3	8
<i>3C48</i>	10^9 *	$< 10^{22}$	$\sim 10^{42}$	10^4	28
<i>3C273B</i>	5×10^8 *	$< 2 \times 10^{21}$	$\sim 4 \times 10^{43}$	10^3	98

* Assuming redshift is cosmological.

Fig. 1. Optical continua of NGC 4151 (full line), η Carinae (dashed line), Crab Nebula (filled circles), 3C48 (small open circles) and 3C273B (large open circles).

observations of surrounding field stars, the total absorption amounting to 1.10 magnitudes. The photometric observations were corrected for the presence of emission lines due to the filamentary component of the Crab, but the corrections do not exclude noticeable amounts of Balmer recombination continuum at wave-lengths below 3647 Å. Recent unpublished scanner measurements of the Crab by Oke agree in general with O'Dell's observations; but show some evidence for an increase in flux in the Balmer continuum.

We have also plotted, in Fig. 1, Baum's⁸ measurements of the monochromatic fluxes at several wave-lengths for 3C48. These relatively broad band observations have not been corrected for the presence of emission lines but have been reduced to the laboratory frequency system by applying the appropriate redshift corrections for a Doppler displacement factor of 1.367. Again, unpublished scanner observations by Oke show good agreement with those of Baum.

Among the quite diverse objects represented in Fig. 1, there appears to be a remarkable similarity in the radiated optical continua longward of 4000 Å. There are obviously varying contributions of Balmer recombination continua at shorter wave-lengths which correlate well with the observed equivalent widths of H β as listed in Table 1. The resemblance of the overall continua of NGC 4151 and η Carinae is particularly striking in view of their dissimilar nature.

Although the objects so far discussed do have a common slope, it is also clear that there are other objects where this is not strictly the case. As an example, the continuous spectrum of 3C273B as measured by Oke⁹ is much flatter in the blue spectral region, although, as shown in Fig. 1, there is some suggestion that, in the near infrared, the continuum slope of 3C273B approaches that of the other objects represented in Fig. 1. Furthermore, unpublished observations by Oke have shown that other Seyfert nuclei, NGC 1068 and NGC 1275, have considerably redder continuum slopes than NGC 4151; this may be caused by the presence of cool stars in the former.

The point we wish to emphasize is that for all the objects in Fig. 1, there appears to be a common contribution to the spectrum which dominates the Paschen continuum and for which $F(\nu) \propto e^{-\alpha\nu}$ where $\alpha \approx 2.4 \times 10^{-15}$ c.g.s. units. It implies the existence of a common physical process occurring in gas masses which experience violent internal motions. The cases of η Carinae and the Crab Nebula show that this process is not essentially connected with the behaviour of gas masses on a galactic scale.

Shklovsky¹⁰ has proposed that the optical continuum of the Crab Nebula is synchrotron radiation; Mathews and Sandage¹¹ have ascribed the whole of the optical continuum of 3C48 to this process; and Oke⁹ also discusses the red continuum of 3C273B in terms of optical synchrotron

radiation. In all cases the optical spectral index is larger than that found from the radio observations and the difference has been attributed to the effect on the optical fluxes of a high-frequency cut-off in the electron energy spectrum. It is remarkable that in such dissimilar objects so great a uniformity should obtain in the processes which determine the energy spectrum of the relativistic electrons.

If the continua are produced by synchrotron radiation we could hope to detect polarization, given a favourable magnetic field geometry in the objects. The co-existence of a recombination spectrum and a synchrotron spectrum in η Carinae and NGC 4151 would lead one to expect more polarization in the red than shortward of the Balmer jump. In the case of η Carinae, Visvanathan¹² has examined the polarization first observed by Thackeray¹³ and has shown it to be independent of wave-length. This is in contrast to the effect of interstellar polarization, but neither is it to be expected on the synchrotron hypothesis. Investigations of polarization and particularly its wave-length dependence in these violent objects are obviously of great importance in the further understanding of this problem.

Growth of Interstellar Grains

IN a previous communication¹ we obtained an expression for the rate of growth of interstellar grains moving relative to a gas or to a cloud of grains. The main assumptions were that the grain remained spherical during growth and its size remained small in comparison with the mean free path of the gas molecules, thus enabling the velocity distribution of the molecules to be taken as an equilibrium, in this case Maxwellian, distribution. We also assumed that a fixed proportion, λ , of the colliding gas molecules adhered to the grain.

In order to obtain the actual size of the grain at any instant, we made the further assumption that the speed of the grain remained constant throughout the motion, and was not affected by collisions with the gas molecules. In this communication we dispense with this assumption and take into account the effects of retardation by making use of the formula for the resistance to the motion of small spheres given by Baines, Williams and Asebiomo².

In ref. 1 the rate of increase of the mass M of the grain moving at any speed U through the gas was found to be:

$$\frac{dM}{dt} = 2\pi m n a^2 \lambda \left(\frac{\beta}{\pi}\right)^{\frac{1}{2}} \left\{ \frac{e^{-\beta U^2}}{2\beta} + \left(\frac{U}{2} + \frac{1}{4\beta U}\right) \left(\frac{\pi}{\beta}\right)^{\frac{1}{2}} \operatorname{erf}(\sqrt{\beta} U) \right\} \quad (1)$$

where erf denotes the error function (see, for example, ref. 3). The gas, which consists of n molecules, each of mass m , per unit volume, is assumed to have a kinetic temperature T and as usual we write $\beta = m/2kT$, where k is Boltzmann's gas constant. We found that equation (1) could be written most simply in terms of a non-dimensional molecular speed ratio:

$$S = \sqrt{\beta}U = \frac{2U}{\sqrt{\pi W}}$$

where W denotes the mean thermal velocity of the gas molecules, in the form:

$$\frac{dM}{dt} = mna^2\lambda\left(\frac{\pi}{\beta}\right)^{\frac{1}{2}}\left\{e^{-S^2} + \left(S + \frac{1}{2S}\right)\sqrt{\pi}\text{erf}(S)\right\} \quad (2)$$

Now the resistance to the motion of a small sphere moving through a gas has been calculated in ref. 2 to be:

$$R_S = mna^2\frac{\sqrt{\pi}}{\beta}\left\{\left(S + \frac{1}{2S}\right)e^{-S^2} + \left(S^2 + 1 - \frac{1}{4S^2}\right)\sqrt{\pi}\text{erf}(S)\right\} \quad (3)$$

on the assumption that all the molecules are reflected ($\lambda = 0$), and that the reflexion is specular. (In specular reflexion the component of velocity perpendicular to the surface of collision is reversed while the other component remains unchanged.) Although in the growth problem a proportional λ of the molecules adhere to the sphere, it can be shown using the appendix to ref. 2 that molecules reflected specularly from the sphere carry off no momentum on the average. No modification is therefore required to equation (3) when $\lambda \neq 0$.

The equation of motion for the grain, assuming specular reflexion for the molecules not adhering, is:

$$\frac{d}{dt}(MU) = -R_S$$

and since $S = \sqrt{\beta}U$, we obtain:

$$\frac{d}{dt}(MS) = -\sqrt{\beta}R_S \quad (4)$$

Now:

$$\frac{d}{dM}(MS) = M\frac{dS}{dM} + S$$

or

$$d(MS)/dM = S + 1/\{d(\log M)/dS\} \quad (5)$$

From equations (5), (4), (3) and (2) we can evaluate

$$\frac{d}{dS}(\log M)$$

in terms of S , and integration then gives:

$$\log\left(\frac{M_2}{M_1}\right) = -\int_{S_1}^{S_2}\left[S + \frac{1}{\lambda}\left\{\frac{\left(S + \frac{1}{2S}\right)e^{-S^2} + \left(S^2 + 1 - \frac{1}{4S^2}\right)\sqrt{\pi}\text{erf}(S)}{e^{-S^2} + \left(S + \frac{1}{2S}\right)\sqrt{\pi}\text{erf}(S)}\right\}\right]^{-1}dS \quad (6)$$

where M_1 and M_2 are the masses of the grain for speed ratios $S = S_1$ and $S = S_2$, respectively.

The integration in equation (6) can be carried out numerically. Alternatively, we may approximate to the exponential and error functions in the integrand as in refs. 1 and 2 by using the first few terms of the expansions for large and small S as appropriate (see, for example, ref. 3). The integral can then be evaluated and a simple analytic expression obtained.

For $S \geq 1.4$ we may replace the numerator of the fractional expression in equation (6) by $\sqrt{\pi}(1+S^2)$ and the denominator by:

$$\sqrt{\pi}\left(S + \frac{1}{2S}\right)^*$$

* The first equation in the limiting case (ii) in ref. 1 should contain an additional factor $(\sqrt{\pi}/2)$.

while for $S \leq 1.4$ the numerator can be replaced by:

$$\frac{8}{3}\left(S + \frac{S^3}{5}\right)$$

and the denominator by:

$$2\left(1 + \frac{S^2}{3}\right)$$

Equation (6) then becomes:

$$\log\frac{M_2}{M_1} = -\int_{S \geq 1.4}^{\infty}\left\{1 + \frac{2}{\lambda}\frac{(1+S^2)}{(1+2S^2)}\right\}^{-1}\frac{dS}{S} - \int_{S \leq 1.4}^{\infty}\left\{1 + \frac{4}{5\lambda}\frac{5+S^2}{3+S^2}\right\}^{-1}\frac{dS}{S} \quad (7)$$

and integration gives:

$$\left.\begin{aligned} \frac{M_2}{M_1} &= \left(\frac{S_2^2 + a/b}{S_1^2 + a/b}\right)^{-\lambda/ab} \left(\frac{S_2^2}{S_1^2}\right)^{-\lambda/2a} & S_1, S_2 \geq 1.4 \\ \text{or} \\ \frac{M_2}{M_1} &= \left(\frac{S_2^2 + 5c/d}{S_1^2 + 5c/d}\right)^{-4\lambda/cd} \left(\frac{S_2^2}{S_1^2}\right)^{-3\lambda/2c} & S_1, S_2 \leq 1.4 \end{aligned}\right\} \quad (8)$$

where for convenience we have written $a = \lambda + 2$, $b = 2\lambda + 2$, $c = 3\lambda + 4$ and $d = 5\lambda + 4$. If the speed range extends over both $S \geq 1.4$ and $S \leq 1.4$ both formulae are required, the range being split accordingly. The loss of accuracy has been discussed in detail in ref. 2, and in the present case is scarcely enough to affect three-figure accuracy.

If we make the more drastic approximation of keeping only the first term in the expansions of the numerator and denominator in equation (6) for large and small S , the loss of accuracy may be greater. The corresponding analytic expressions are, however, very simple, and equation (7) becomes:

$$\left.\begin{aligned} \frac{M_2}{M_1} &= \left(\frac{S_2^2}{S_1^2}\right)^{-\lambda/(\lambda+1)} = \left(\frac{U_2}{U_1}\right)^{-\lambda/(\lambda+1)} & S_1, S_2 \geq 1.4 \\ \frac{M_2}{M_1} &= \left(\frac{S_2^2}{S_1^2}\right)^{-3\lambda/(3\lambda+4)} = \left(\frac{U_2}{U_1}\right)^{-3\lambda/(3\lambda+4)} & S_1, S_2 \leq 1.4 \end{aligned}\right\} \quad (9)$$

As the speed ratio S_2 drops to zero the grain clearly grows without limit. However, our model is restricted: (a) by the size of the grain being small compared with the mean free path of the gas; (b) by the neglect of the thermal motion of the grain itself, which implies a minimum speed ratio of the order of 10^{-5} . In calculating the growth we have therefore confined ourselves to speeds with a lower limit of $S = 10^{-5}$, while for the upper limit we chose $S = 10^3$, as this implies an actual speed of the order of 10^8 cm/sec, which is unlikely to be exceeded.

Tables 1 and 2 show the ratio of the final mass to the initial mass as given by equation (8) for grains slowing down from initial speed ratios $S_1 = 1, 10, 10^2, 10^3$ to final speed ratios $S_2 = 10^{-3}, 10^{-2}, 10^{-1}, 10^{-5}$. Table 1 has been constructed using $\lambda = 1$, and Table 2 using $\lambda = 1/10$, in both cases using the equations (8) resulting from the two-term approximation for the functions in equation (6).

Tables 1 and 2 RATIO OF FINAL TO INITIAL MASSES FOR VARIOUS RANGES OF S , USING EQUATIONS (8)

Table 1, $\lambda = 1$					Table 2, $\lambda = 1/10$				
Initial speed ratios, $\log_{10} S_1$	-1	0	1	2	3	-1	0	1	2
	2.68	7.25	21.9	69.3	219	1.17	1.38	1.68	2.07
	7.20	19.5	58.8	186	588	1.38	1.62	1.97	2.43
	19.3	52.2	158	499	1,580	1.62	1.91	2.32	2.86
	51.8	140	423	1,340	4,230	1.91	2.24	2.72	3.35
						2.24	2.54	3.02	3.52
						3.02	3.35	3.82	4.13
						3.82	4.13	4.52	4.82
Final speed ratios, $\log_{10} S_2$	-2	-3	-4	-5		-2	-3	-4	-5

From Tables 1 and 2 the mass ratio can be calculated for any two speed ratios of the form 10^n where n lies between 3 and -5 . To illustrate this point, we note:

$$\frac{M_2}{M_1} (S_1 = 10^2, S_2 = 10^{-1}) = \frac{\frac{M_2}{M_1} (S_1 = 10^2, S_2 = 10^{-3})}{\frac{M_2}{M_1} (S_1 = 10^{-1}, S_2 = 10^{-3})}$$

The maximum growth obviously occurs when $\lambda = 1$ and the change in the speed ratio is greatest, namely, when it drops from $S_1 = 10^3$ to $S_2 = 10^{-5}$. This gives a ratio of the final to the initial mass of just over 4×10^2 . For the same speed ratios and $\lambda = 1/10$ the corresponding ratio of masses is only 5.

In view of the simplicity and ease of application of the formulae in equations (9) we also calculated the ratio of final to initial masses using these formulae, for the same range of parameters as already mentioned. The percentage differences between these results and those given in Tables 1 and 2 were then calculated. The greatest percentage difference for any of the situations considered was only 1.4 and we therefore deduce that equations (9) are perfectly satisfactory for two-figure accuracy.

Finally, we remark that appreciable growth of a grain moving through interstellar gas cannot occur before its relative motion is lost if less than one in ten of the colliding molecules adhere to it. Moreover, for most astrophysical problems a good estimate of the growth is given by the simple formulae in equations (9).

We thank M. A. Mustafa for assistance with the calculation.

RADIOPHYSICS

Anomalous Intensity Ratios of the Interstellar Lines of OH in Absorption and Emission

WE have previously found¹ intensity ratios of the four microwave lines of OH in disagreement with the theoretical and laboratory ratios² of 1 : 5 : 9 : 1 for the lines at 1,612, 1,665, 1,667 and 1,720 Mc/s. For the strong OH absorption of the radio source Sagittarius A it appeared that the ratios might be attributed to high opacity³. We now report a more detailed series of measurements which shows that high opacity alone cannot account for the observations and that disturbed populations of the levels have to be invoked.

Weaver *et al.*⁴ have recently announced the discovery of narrow-band emission at 1,665 and 1,667 Mc/s in ionized hydrogen regions. The emission at 1,665 Mc/s is usually the stronger, and the excess emission is attributed to an 'unidentified microwave line'. We have observed emission from a number of sources at all four OH frequencies, and conclude that all the emission is produced by OH molecules. Weinreb *et al.*⁵ have expressed the same opinion from observations of three of the four lines in the radio source W3. The intensity ratios of the emission lines are abnormal, but can be explained as extreme cases of perturbation of the populations.

Anomalous intensity ratios for all four OH lines in absorption have been measured with the Australian 210-ft. telescope at many points in the complex region near the galactic centre. The ratios vary widely, as is illustrated by the examples in Table 1; there is one case where the absorption on 1,665 Mc/s exceeds that on 1,667 Mc/s. The marked inequality of the absorption at 1,612 and 1,720

* More accurate measurement of value reported earlier¹.

Mc/s is clear evidence for a disturbance of the populations. Recent observations of the nebula RCW 38 have shown weak absorption with ratios of 3 : 3 : 1 for the lines at 1,665, 1,667 and 1,720 Mc/s; thus the anomalous ratios are not confined to the galactic centre region nor to cases of high opacity.

Our first evidence of OH in emission came from observations in the direction of $l=0^\circ 40'$, $b=0^\circ$ in June 1964. Fig. 1 shows the profiles at 1,612, 1,665, 1,667 and 1,720 Mc/s over the radial velocity range -80 to $+120$ km/s, measured with the 37 kc/s filters of the multichannel line receiver. These spectra are blends of absorption lines except for a reversal at about $+70$ km/s on the 1,665 Mc/s profile and possibly on 1,612 Mc/s. That this is emission and not just lack of absorption is clearly demonstrated by observations with 10 kc/s band-width, shown in Fig. 2. In this case the 1,665 Mc/s peak breaks up into at least four components. The principal feature is an emission peak of aerial temperature 36° K and line width not noticeably greater than the experimental band-width. An absorption feature at $+64$ km/s and additional features at $+75$ and $+78$ km/s are visible on three of the profiles in Fig. 2. The source of OH line emission was found to be centred at $l=0^\circ 40' \pm 2'$ and $b=0^\circ 2' \pm 2'$; its angular size is less than the experimental limit of $5'$ of arc.

We have observed nine other thermal radio sources, including three of the sources where emission at 1,665 and 1,667 Mc/s is reported by Weaver *et al.*⁴.

Fig. 1. Line profiles observed at the four OH frequencies in the direction $l=0^\circ 40'$, $b=0^\circ$, with a band-width of 37 kc/s. A sharp emission feature is found at 1,665 Mc/s and possibly at 1,612 Mc/s, on the edge of the broad absorption

For *W49* very strong emission was observed at 1,665 and 1,667 Mc/s, as seen in Fig. 3. Two main peaks were resolved with the 10 kc/s filters, the higher velocity peak being visible on all four OH frequencies. The 1,612 Mc/s profile closely resembles that at 1,665 Mc/s, but the +16 km/s feature is displaced on the 1,667 and 1,720 Mc/s profiles. The intensity ratios of the main emission peaks are 1:19:5:0.3 and 1:11:46:0.4. The line emission source coincides in position with the western (thermal)

Fig. 2. Detail of the profiles of Fig. 1 over the velocity range 60–85 km/sec. These measurements were made with 15 channels of band-width 10 kc/s. Profiles for each of the OH lines have been superimposed. The zero levels for the four profiles are marked on the ordinate

Fig. 3. Emission from the nebula *W49* at each of the four OH frequencies. The aerial temperatures for 1,665 and 1,667 Mc/s reach high values, and the intensity scale for these profiles has been reduced by a factor of 5

component of the double source. The OH emission is not resolved with the 12-min beam, and so must have an angular size less than 5 min of arc. The observed peak antenna temperature of 140° K at 1,665 Mc/s would thus correspond to a brightness temperature of over 800° K.

For *NGC 6334* a complex emission feature was observed near -10 km/s at 1,665, 1,667 and 1,720 Mc/s, the peak temperature being 33° K at 1,665 Mc/s. Pronounced absorption occurred on all four frequencies near -3 km/s. The line emission is clearly displaced by 4 min of arc to the east of the continuum maximum, coinciding with the edge of one of the bright condensations of the nebula. Again the OH source is unresolved with the 12 min of arc beam.

OH emission was seen in the directions of the Orion nebula, η Carinae, *MHR49* (R.A. 16 h 09 m 34 s, Dec. -57° 20' 5) and possibly *NGC 6357*. We found no emission in *RCW38*, *RCW49*, *RCW57*, 30 Doradus or the Crab Nebula.

Weaver *et al.*⁴ have suggested that some or all of the emission near 1,665 Mc/s was an unidentified microwave line. Their argument was based on the finding that the emission at 1,665 Mc/s was stronger than that at 1,667 Mc/s, that the profile shapes on the two lines were very different, and that no counterpart to the 1,665 Mc/s emission in *W49* could be found at 1,612 Mc/s. They explain the anomalous 1,665 Mc/s emission in *W49* and *NGC 6334* as a blend of the OH line and the line of 'mysterium' (with a slightly higher rest frequency).

In *W49* we find that the 1,665 Mc/s profile is closely reproduced at 1,612 Mc/s. Related emission features are also seen on 1,667 and 1,720 Mc/s. We have also observed emission at all four OH frequencies near $l=0^\circ 40'$, $b=-0^\circ 02'$, and Weinreb *et al.*⁵ have observed emission at 1,665, 1,667 and 1,720 Mc/s near the nebula *W3*. The intensity ratios are 'abnormal', but as anomalous ratios are also found in many of our absorption measurements we conclude that both phenomena are produced by OH molecules the populations of which are disturbed from the equilibrium values. The high brightness temperatures of the emission also support the argument for departures from equilibrium.

The Berkeley and Massachusetts Institute of Technology observations show that the emission profiles have many extremely narrow-band components, some as narrow as 1 kc/s. If the intensity ratios are different for each of the components, we would expect the composite profile to have different overall shapes on each of the frequencies.

High molecular densities would be required to explain the observed emission as spontaneous emission from excited molecules. Further, all cases of OH emission are seen against a strong continuum background, when stimulated transitions would be the dominant term in the equation of transfer unless the excitation temperature exceeded the brightness temperature of the continuum. If the populations were inverted, the background could be amplified; then lower OH densities would suffice and narrow lines would be produced.

The anomalous OH emission or absorption has been found only in some ionized hydrogen regions. As the nebulae have appreciable internal motions, the narrow lines imply that the emitting regions are of small size and low kinetic temperature. In *W49* and *NGC 6334* we find that the emitting region is small and displaced to the edge of the nebula. The selective excitation of the molecules may be due to radiation from these bright nebulae. Alternatively the OH molecules might be formed near the ionized region and not all reach equilibrium before they are dissociated or involved in other reactions. A possible mechanism for forming excited OH molecules in the $^2_1I_{3/2}$ state has been proposed by Dr. J. L. Symonds (following communication) involving capture of protons by negative oxygen ions. The energy-levels of the resulting molecules might also be perturbed, thus modifying the

natural rest frequencies. With very weak magnetic fields the molecules so formed could give emission that is polarization sensitive. This could explain the observations⁵ of linearly polarized emission in some features without the need for a magnetic field strong enough to separate the components by Zeeman splitting.

We thank Prof. W. A. Fowler and Prof. V. H. Rumsey for their advice. We also thank Mr. J. D. Murray for modifications to the receiver.

Formation of Hydroxyl Molecules in Interstellar Space

DURING the past year, radio astronomers^{1,2} have been increasingly interested in microwave signals at frequencies of 1,612, 1,665, 1,667 and 1,720 Mc/s, produced by transitions between four energy levels of the OH molecule in the $^2\Pi_{3/2}$ state. Theoretical and laboratory intensity ratios³ for the four microwave lines were found to be 1 : 5 : 9 : 1. It was reported¹ recently that anomalous intensity ratios had been measured in the strong OH absorption lines of the radio source Sagittarius A. McGee *et al.*⁴ have extended their measurements to other radio sources and find emission and absorption at all four frequencies with instances of extremely anomalous intensity ratios.

Emission and absorption lines showing such anomalous intensity distributions indicate unusual populations of energy levels in the OH molecules. The observed distributions are more like those expected of a chemical reaction mechanism, followed by radiative deactivation, rather than those from thermal excitation. Since the gases are tenuous in the regions which produce these signals, the long time-scale between collisions will give the molecules, formed in an excited state, a greater probability of radiative rather than collisional de-activation.

The process of association of two atoms to form a molecule normally has a low probability. Since atomic recombination is known to proceed more rapidly in the presence of a third body, 'dust' grains in space have been suggested as a suitable medium. The tenuous nature of the gas would seem to rule out a three-body process, however, and such reactions do not appear likely to produce the observed intensity anomalies. The processes for production and loss of OH molecules by two-body processes, therefore, deserve closer study.

In relation to the known concentrations of oxygen and hydrogen in our galaxy, the concentration of OH molecules is such as to make it improbable that they are all formed by the direct collision process between atoms. In the study of gaseous processes in flames by spectroscopic means, OH spectra show evidence of pre-dissociation, made possible by radiationless transitions between states of nearly the same energy where the potential energy curves of the states cross or approach closely. The inverse pre-dissociation process⁵ (pre-association) is also possible for forming molecules from a two-body collision. The pre-dissociation of the OH molecule to O and H atoms and its inverse are believed to occur, but with a small

probability, because a normally forbidden transition is involved.

It is suggested that other two-body processes should be investigated for an alternative mechanism. Since the atom recombination is low, a mechanism worthy of consideration is the exothermic association of negative oxygen ions, O⁻, and positive ions of hydrogen, H⁺ (protons).

The presence of O⁻ ions seems assured by the strong electron affinity of oxygen (1.45 eV) and the known presence of oxygen atoms in the regions under study. The anomalous emission and absorption has only been found in ionized regions^{4,6} where large concentrations of electrons and protons must also exist. The pre-association of O⁻ and H⁺ essentially may be a transition from the coulomb potential energy curve to the $^2\Sigma^+$ or, more probably, the $^2\Pi_{3/2}$ state curve, involving charge transfer. The interaction cross-section should have a maximum value when the relative velocity of the two ions produces kinetic energy close to the differences between the binding energy of the OH molecule and the electron affinity of the oxygen atom, that is, $\epsilon = 45 - 1.45 = 3 \text{ eV}$.

In such circumstances, it is possible to form OH molecules in the $^2\Pi_{3/2}$ state with the population of each of the four levels depending greatly on the relative velocity of the O⁻ and H⁺ ions. Whether the molecules emit or absorb energy will depend on the populations of the energy levels and, in bulk, one would not expect to see the theoretical intensity ratios. Situations could arise where the relationships between lines were completely unusual, for example, apparent absorption in some of the four lines and emission in the others. The actual result will depend strongly on the relative velocity distribution of the two ions. Investigation of the intensity ratios may, therefore, give a great deal of information on relative ion velocities.

Since the reaction has a 'resonance' character, it will favour relative velocities producing about 3-eV kinetic energy between the ions. If the O⁻ ion were stationary, the proton velocity would need to be about 25 km/sec, which is certainly in the range found in the ionized regions of the galaxy. The lack of emission or absorption at the four frequencies in galactic regions of lower temperature may be explained in terms of a low cross-section at proton velocities well below 25 km/sec. An accurate calculation of the reaction cross-section and the state of the resulting molecule would be informative.

The process of association between O⁻ ions and protons, or for that matter any similar process between other ions, does not appear to have received great attention. The study of recombination rates in flames⁶ shows evidence of a non-equilibrium condition in the excitation of molecules and atoms in the flame. Unexplained concentrations and intensity ratios exist which relate to OH molecule formations. These conditions may be the result of ionic recombination to form molecules and not atom-molecule reactions. Evidence of strong negative and positive ion concentrations has been found^{7,8}, but the result of their presence on the state of excitation of product molecules has not been elucidated.

If the reaction mechanism is as proposed, radiationless transitions will leave the OH molecule with a velocity similar to that of the O⁻ ion. However, it is not obvious what the 'temperature' of the O⁻ ions will be since their velocity will depend on their mode of formation and their lifetime.

Two effects must be studied. First, the OH line will be shifted by Doppler effects resulting from mass motion relative to the observational point, and the mass motion may not necessarily be related to the motion of the O and H atoms. Secondly, the line broadening may differ from that produced by the 'temperature' of the surrounding ionized gas region because the radiationless transitions occurring in pre-association results in some perturbation

of the rotational levels in the states involved. Corresponding shifts in line positions and changes in the intensity distributions will occur, with widths also being reduced in the process.

Orientation of the magnetic moment of the O⁻ ion by a magnetic field should produce a modification of intensity ratios, possibly an alteration of frequency not associated with a mass movement, and certainly polarization effects. Viewing the OH radiation coming from an ionized region, the proposed mechanism suggests that the radiation will be linearly polarized¹⁰ since the movement of hydrogen appears to be radially outward and the axis of rotation of the OH molecules will tend to be in a plane normal to the proton direction.

The known presence of OH molecules must also lead to the assumption that OH⁻ molecular ions are also present. The electron affinity of the OH molecule is greater than that of the oxygen atom, making possible two reactions of interest. The first is similar to that for the formation of OH and would lead to the formation of the H₂O molecule. The second is the charge transfer process which will result in the production of an atom of hydrogen and an excited OH molecule. Apart from ionizing and other processes which remove OH molecules, it is obvious that there are other modes of OH formation by collision processes between ions, atoms and molecules which must be taken into account.

Finally, the proposed mechanism offers some interesting prospects in relation to the formation of other molecules. Atoms with strong electron affinities are more likely to produce similar reactions with protons. Equally, the rotational states of such molecules will be excited. Atoms of hydrogen, carbon, oxygen, silicon and sulphur would be capable of forming negative ions. Whether the pre-association process is possible is not known for every case. Since nitrogen does not form a stable negative ion, NH may not be observed. Nevertheless, similar reactions may take place between N⁺ and O⁻ or C⁻ to give NO and CN molecules.

The formation of H₂ from H⁻ and H⁺ ions may require higher relative velocities, but the cross-section for H⁻ production from H is four orders of magnitude less than for O⁻ formation. Such a process may not be observable in this count alone, without invoking the question of the frequency range in which signals may be expected.

In summary, the association mechanism appears to offer some prospect of success in accounting for the anomalous intensity ratios; the emitted radiation may well be linearly polarized if a magnetic field is present; some suggestions can be made as to kinds of molecules that might be formed. More theoretical and experimental work on reactions between negative and positive ions appears to be necessary to establish their importance.

I thank Dr. B. J. Robinson and his colleagues of C.S.I.R.O. Radiophysics Laboratory for their advice and for making available the results of their investigations before publication.

PHYSICS

Laminar and Turbulent Flow in Open Channels

IN a paper published in 1884, Prof. Osborne Reynolds¹ expressed the opinion that free surfaces, as found in open channels, tend to be "conducive to direct or steady motion". Thus we should expect the critical Reynolds number for open channels to be, in general, higher than it is for pipes, using the hydraulic radius as the length-parameter throughout.

This view would appear to be borne out by the results of recent work carried out here, in which channels of narrow rectangular and T-shaped cross-sections were used. Further confirmation is supplied by a study of the investigations quoted in Table 1.

It will be appreciated that an analysis of laminar and turbulent flow is considerably more difficult for open channels than for circular sectioned pipes, since (a) only channels having the same width to depth ratio are geometrically similar, while (b) the symmetry of the velocity distribution which occurs in flow through circular pipes cannot be assumed for the more complex pattern of flow encountered in channels. This is particularly true of narrow channels in which the drag of the side-walls has a great influence.

It is tentatively suggested after an examination of Table 1 that the dimensionless group $\frac{\sigma}{\rho^2 \rho} (= \frac{f}{2})$, is

* From the curve of f against Reynolds number where available.

† There seems to be some doubt whether this was a lower critical number.

of paramount importance in determining the laminar or turbulent nature of the flow. Thus it seems that $f/2$ has a reasonably constant critical value irrespective of the shape of the cross-section.

A physical interpretation of the significance of the factor $\sigma/\rho\bar{v}^2$ is that it represents the ratio of the shearing stress at the solid boundary to the momentum per unit area of the section. In the early stages of laminar flow the shearing stress σ is sufficient to ensure that eddies are not created, but if the mean velocity \bar{v} then rises gradually, the denominator, $\rho\bar{v}^2$, increases more rapidly than the numerator σ , thus causing a drop in the value of f which continues until a stage is reached, marking the onset of turbulence, when the shearing stress is insufficient to overcome the effects of the inertia. Further resistance is then developed in the form of eddies.

ENGINEERING

Detonability of Nitroglycerin contained in Porous Rock

In the course of experiments to determine the feasibility of using liquid explosives to enhance the productivity of oil- and gas-bearing sandstones after hydraulic fracturing, it has been found that dry porous sandstone could imbibe sufficient nitroglycerin-ethylene glycol dinitrate (50-50 NG-EGDN¹) to yield a detonable charge.

The rock used was Berea sandstone of density 2.2 g/cm³ when dry. Imbibition tests with both water and NG-EGDN showed that this rock is capable of holding 11-13 per cent of its own volume of liquid, although comparison of its bulk density with that of crystalline silica indicates that about 17 per cent of the rock volume is void space.

The rock samples were 2 × 2 × 6-in. blocks which were dried at over 100° C for more than 16 h. They were then immersed in NG-EGDN for several hours. It was found that the rock absorbed 6.6-7.4 per cent by weight of the explosive after 2 h immersion, and that this could be increased to 8.2 per cent by immersion for 48 h.

The detonability trials were instrumented with an expendable pressure transducer having a useful range of 1-70 kbar located at the downstream end of the charge and a continuous, pressure-actuated detonation velocity probe for measuring detonation rates along one side of the charge. Data were recorded oscillographically.

The initiator consisted of a No. 8 electric blasting cap and either a 7.5 or 15-g tetryl pellet (0.75 in. diam. × 0.5 in. long or 0.75 in. diam. × 1.0 in. long); in one case which detonated, there was an additional booster consisting of a reservoir of NG-EGDN 2 in. square and 0.75 in. deep, holding 73 g. For each trial using NG-EGDN, a corresponding test was made using water as the imbibed medium in order to determine the response of the instrumentation to the inert shock transmitted from the donor. In no case was this shock sufficient to actuate the instrumentation, although the sandstone, which was quite fragile, was completely shattered.

Samples with up to 7.4 per cent NG-EGDN did not detonate, although it is possible that the booster was inadequate in these cases. With the NG-EGDN reservoir and with a sample that had absorbed 8.2 per cent NG-EGDN, the measured detonation rate was 4.7 mm/μsec. The record from the pressure transducer was slightly obscured by electrical ringing, but a pressure in excess of 25 kbar was indicated.

Thus, it appears that nitroglycerin, absorbed into a solid, porous, inert matrix, is detonable in concentrations as low as 8 per cent by weight; the resulting system, while insensitive, has an unexpectedly high velocity of detonation. This may be compared with the behaviour of gelled NG absorbed in sodium chloride (density 1.37 g/cm³) where the detonation rate with 15 per cent NG in 4.45-cm diam. is 1.55 mm/μsec (ref. 2).

CRYSTALLOGRAPHY

Structure of Calcium Oxalate Monohydrate

ALTHOUGH details of the structure of some of the hydrates of calcium oxalate have been reported^{1,2}, the monohydrate is less amenable to crystallographic analysis, since the synthetic salt³ precipitates as a finely divided powder and the naturally occurring mineral whewellite usually contains impurities^{4,5}. Calcium oxalate occurs widely in biological subjects, however, and in plants, where X-ray diffraction powder diagrams have been used to distinguish the various hydrates^{6,7}; crystals of optically visible size are commonplace⁸. In the course of our investigation of the nature of calcium oxalate in plants, we have been able to isolate crystals of the monohydrate of sufficient size to permit complete measurement of the lattice.

The crystals used in the work recorded here were separated from the leaves and stems of *Yucca rupicola* Scheele collected from a native habitat near Oak Hill, Texas. Calcium oxalate monohydrate is present as an intracellular deposit⁹, either in the form of solitary styloids (in the case of the largest crystals) or as smaller needle-shaped crystals in the raphide bundles. The crystals were prepared by triturating the chopped tissue in 95 per cent ethyl alcohol in a high-speed blender, followed by filtration through coarse muslin to remove cellular debris. The filtrate was centrifuged to separate the denser oxalate from the lighter organic substances and the precipitate was resuspended in fresh alcohol and recentrifuged repeatedly until the sediment consisted principally of whole or broken crystals. Samples of the total sediment, and samples of representative groups of the larger crystals selected with a fine glass needle, were examined in a cylindrical X-ray diffraction powder camera. A few specimens of the largest and most perfect crystals, up to 200 μ long, were selected under a low-power polarizing binocular microscope, mounted on a fine glass fibre and subjected to single crystal analysis.

Single crystal X-ray diffraction data obtained with Weissenberg and precession cameras using copper K_α and molybdenum K_α radiation can be indexed on the basis of a monoclinic cell; $a = 6.61 \text{ \AA}$, $b = 14.46 \text{ \AA}$, $c = 10.07 \text{ \AA}$ and $\beta = 116.5^\circ$. The $\theta 0l$ diffraction data permit also the choice of $\beta = 109.4^\circ$ which is closer to the previously reported values of 107° ; the cell parameters then become $a = 6.28 \text{ \AA}$, $b = 14.46 \text{ \AA}$ and $c = 11.10 \text{ \AA}$. There are eight formula weights in the unit cell and the calculated

density of 2.254 compares favourably with the densities recorded elsewhere. Observed systematic extinctions occurred for $h0l$ when l is odd and for $0k0$ when k is odd.

The space group is thus P_{21}^2/c . The $hk0$ Weissenberg diagram shows that festoons of spots whose k index is divisible by 4 are very strong while the spots lying along curves of different k values are either missing or extremely weak. Thus the calcium atom appears to lie near $y = 1/4$. In Table 1 our X-ray diffraction results are compared with axial ratios and β -angles deduced from optical measurements reported previously.

Table 1. COMPARISON OF AXIAL RATIOS AND β -ANGLE OF CALCIUM OXALATE MONOHYDRATE

	a, A	a/b	b, A	b/b	c, A	c/b	β°

The powder diffraction pattern of our material compares closely with the pattern of Montana whewellite reported by Pecora and Kerr¹³. In agreement with these authors, we can find no diffraction lines greater than 5.95 Å in any of our specimens, in contrast to the data recorded by Gude *et al.*⁵ which include a line at 14.3 Å indexed as (101) and a line at 10 Å indexed as (001). Since both these

lines cannot occur in the space group P_{21}^2/c , their presence may be explained by polymorphism, by alteration of space groups by variation in the ratio of water to oxalate, or by impurities such as mica or chlorite.

This work was supported in part by National Science Foundation grant GB 1458 and by National Institutes of Health grant 5T1GM789; a complete structure analysis will be reported in due course.

CHEMISTRY

Thermoluminescence and Ultra-violet Phosphorescence of the Nucleic Acid Bases

THIS communication reports some preliminary experimental results obtained from a study of:

(1) Thermoluminescence induced in the five nucleic acid bases following irradiation at 77° K in a cobalt-60 γ -ray source.

(2) Ultra-violet phosphorescence from the same materials at the same temperature, excited by a Hanovia fluorescence model 16 mercury arc lamp.

(1) *Thermoluminescence.* The samples were prepared as cylindrical pellets of diameter 1.25 cm and depth 1 mm, formed under pressures of about 4 tons/in². Following irradiation in silicate glass tubes, in the presence of oxygen, glow curves were recorded using a technique identical to that described by Charlesby and Partridge¹. The temperatures at which the peak light intensities occurred were deduced from traces drawn by a recorder connected to a thermocouple in contact with the emitting surface of the sample facing the photomultiplier.

The doses were varied from 200 rads up to 1.25 Mrads, and in all cases the total light output, taken as proportional to the area under the glow curve, was found to vary directly with the dose. In cytosine three intensity peaks were recorded, and in thymine the persistence of thermoluminescence at temperatures close to 273° K was very marked.

The results are summarized in Table 1, and are compiled from at least four separate determinations. The figures given in brackets under the temperature heading are those obtained by Lehman and Wallace², from a similar investigation. The accuracy of the present measurements is $\pm 10^\circ$ K. Thus it will be seen that the two sets of results agree within experimental error, except in the case of cytosine. This discrepancy may be accounted for by the more precisely controlled warming rates pertaining to Lehman and Wallace's work. We found no evidence for the existence of a second (160° K) glow peak in uracil.

	Peak temperature (° K)	Relative thermoluminescent light yield
Adenine	127 (120 \pm 10)	1
Cytosine	100, 145, 200 (115, 130, 180)	0.01, 0.3, 0.05
Guanine	120 (108 \pm 4)	0.012
Thymine	105 (105)	0.02
Uracil	127 (120, 160)	0.03

A determination of the spectral distribution of the glow curves was attempted, having first established by extensive optical filter experiments that the spectral content of each glow peak of the thermoluminescence emission did not vary appreciably with temperature/time. The results are shown, for adenine and cytosine, in Fig. 1. The curves were obtained using a Hilger and Watts E498 ultra-violet quartz spectrograph, in conjunction with the E720 photoelectric scanning unit manufactured by the same company. Since the thermoluminescence emission continued for, at most, 60 sec after the samples had been removed from the irradiation Dewar vessel, the procedure adopted was to set the scanning unit on the required wave-length (at 250 Å intervals) and determine the total intensity of the emission at that wave-length, taken as proportional to the area under the glow curve, suitably corrected for variation of photomultiplier sensitivity with wave-length. Unfortunately, the light collection efficiency of the spectrometer was not sufficiently high to permit the recording of similar spectral curves for

Fig. 1. Thermoluminescent spectra. ---, Adenine; —, cytosine (145° K peak); - - -, cytosine (200° K peak)

Fig. 2. Phosphorescent spectra. ●, Adenine; ×, thymine

the low intensity emission of guanine, thymine, uracil, and the low temperature (100° K) peak of cytosine.

(2) *Ultra-violet Phosphorescence.* The spectral curves shown in Fig. 2, for adenine and thymine, were obtained using the rotating camera phosphoroscope method first proposed by Lewis and Kasha³. The samples, in crystalline powder form, were contained in continuously rotated quartz test-tubes immersed in liquid nitrogen in a quartz Dewar vessel. The phosphorescence persistence time was approximately 1 sec for adenine, but was less than 0.1 sec in the case of thymine. No phosphorescence was observed from cytosine, guanine, and uracil. These latter results differ from those of Bersohn and Isenberg⁴, obtained for water-glycerine glasses at 77° K. They observed phosphorescence from guanine but not from thymine; the absence of guanine phosphorescence from our experiments may be due to the presence of impurity metal ions in our guanine samples.

The similarity between the thermoluminescence and phosphorescence spectral distribution curves for adenine would appear to indicate that the same luminescence centre is involved in both cases, a conclusion already reached by Singh⁵. Consequently, the absence of phosphorescence in cytosine, contrasting with the relatively strong thermoluminescent glow peaks, is perhaps somewhat surprising. Furthermore, the spectral content differences between the two higher temperature thermoluminescent peaks, at shorter wave-lengths, is the reverse of what might be expected from the greater depth of the electron trap associated with the highest temperature (200° K) glow peak. In the absence of further evidence on the long tail of the thymine glow curve, no explanation of this observation is attempted at present.

Dissociation Energy of the N—H Bond in Hydrazine

THE value of the dissociation energy of the N—H bond in hydrazine is uncertain as there exists a discrepancy between the measured value and that indicated by other chemical evidence.

A value may be obtained from electron impact measurements by means of the relationship:

$$D(\text{H—N}_2\text{H}_3) = A(\text{N}_2\text{H}_3^+) - I(\text{N}_2\text{H}_3)$$

provided that the appearance potential, $A(\text{N}_2\text{H}_3^+)$ from hydrazine, involves no kinetic energy and that the ionization potential, $I(\text{N}_2\text{H}_3)$, is close to the adiabatic value. Dibeler¹ obtained 11.3 ± 0.1 eV for $A(\text{N}_2\text{H}_3^+)$ from hydrazine. We have confirmed this value by independent measurements. In our experiments it was possible to obtain parallel ionization efficiency curves for hydrazine and the calibrating gas only after the hydrazine had been present in the mass spectrometer for several hours.

Dibeler derived an indirect value for $I(\text{N}_2\text{H}_3)$ of 6.2 eV which combined with his value for $A(\text{N}_2\text{H}_3^+)$ gave $D(\text{H—N}_2\text{H}_3) = 115$ kcal/mole. This was later revised to 78 kcal/mole by the use of $I(\text{N}_2\text{H}_3) = 7.88$ eV obtained by Foner² from the direct ionization of the N_2H_3 radical. Other chemical evidence has been suggested by Gray³ to give a value of $D(\text{H—N}_2\text{H}_3) = 91$ –93 kcal/mole. Direct values of radical ionization potentials are difficult to assess, however, and the following arguments are offered in justification of Foner's value for $I(\text{N}_2\text{H}_3)$ and hence the lower value of about 78 kcal/mole for $D(\text{H—N}_2\text{H}_3)$.

An indirect value for $I(\text{N}_2\text{H}_3)$ can be obtained in the following manner. Consider the metathetical reaction:

for which Gray⁴ obtained an activation energy, E_0 , of 5.0 kcal/mole. An overall enthalpy of reaction, $\Delta H_{(1)}$, can be calculated by using Semenov's equation⁵:

$$E_0 = 11.5 + 0.25 \Delta H$$

This gives $\Delta H_{(1)} = -26.0$ kcal/mole. The heat of formation of the hydrazyl radical is given by:

$$\Delta H_f(\text{N}_2\text{H}_3) = \Delta H_{(1)} - \Delta H_f(\text{CH}_4) + \Delta H_f(\text{CH}_3) + \Delta H_f(\text{N}_2\text{H}_4)$$

which leads to $\Delta H_f(\text{N}_2\text{H}_3) = 47.1$ kcal/mole. The heat of formation of the hydrazyl ion is given by:

$$\Delta H_f(\text{N}_2\text{H}_3^+) = A(\text{N}_2\text{H}_3^+) - \Delta H_f(\text{H}) + \Delta H_f(\text{N}_2\text{H}_4)$$

which leads to $\Delta H_f(\text{N}_2\text{H}_3^+) = 230$ kcal/mole. The ionization potential is simply given by the difference:

$$I(\text{N}_2\text{H}_3) = \Delta H_f(\text{N}_2\text{H}_3^+) - \Delta H_f(\text{N}_2\text{H}_3) = 7.9 \text{ eV}$$

in good agreement with Foner's direct value. This procedure for deriving radical heats of formation is somewhat arbitrary but apparently justifiable in that, by similar reasoning, for the reaction:

$I(\text{NH}_2)$ and $D(\text{H—NH}_2)$ so determined are in good agreement with established values. It is interesting to note that, quite independent of any electron impact data, the bond dissociation energy calculated for the reaction:

and given by:

$$D(\text{H—N}_2\text{H}_3) = \Delta H_f(\text{H}) + \Delta H_f(\text{N}_2\text{H}_3) - \Delta H_f(\text{N}_2\text{H}_4)$$

leads to $D(\text{H—N}_2\text{H}_3) = 77$ kcal/mole.

It is possible to calculate the ionization potential of the radical CH_2NH_2 in an analogous manner to $I(\text{N}_2\text{H}_3)$. For the reaction:

Gray⁴ obtained a value of 8.7 kcal/mole for E_0 . Thus $\Delta H_{(2)} = -11.2$ kcal/mole which leads to $\Delta H_f(\text{CH}_2\text{NH}_2) = 32.5$ kcal/mole and $D(\text{H—CH}_2\text{NH}_2) = 91$ kcal/mole. Mass spectra⁶ of the deuterated amines CH_3ND_2 and CD_3NH_2 indicate that hydrogen loss in the dissociative ionization process:

occurs mainly to give the ion CH_2NH_2^+ and not CH_3NH_2^+ . Collin's data⁷ thus give $\Delta H_f(\text{CH}_2\text{NH}_2^+) = 176$ kcal/mole. The value of $I(\text{CH}_2\text{NH}_2)$ is then 6.25 eV.

A similar calculation for the reaction:

leads to $I((\text{CH}_3)_2\text{N}) = 9.45 \text{ eV}$, compared with a value of about 9.1 eV obtained by Gowenlock⁸.

It is possible to assess Foner's value for $I(\text{N}_2\text{H}_3)$ by calculation of the following differences in ionization potentials of isoelectronic radicals:

$$I(\text{NH}_2) \text{ (ref. 2)} - I(\text{CH}_3) \text{ (ref. 9)} = 11.4 - 9.85 = 1.55 \text{ eV}$$

$$I((\text{CH}_3)_2\text{N}) - I((\text{CH}_3)_2\text{CH}) \text{ (ref. 9)} = 9.45 - 7.9 = 1.55 \text{ eV}$$

$$I(\text{N}_2\text{H}_3) - I(\text{CH}_2\text{NH}_2) = 7.9 - 6.25 = 1.65 \text{ eV}$$

It can be seen that the differences between isoelectronic pairs are practically constant, indicating that Foner's value cannot be greatly in error.

Using our value of $A(\text{N}_2\text{H}_3^+) = 11.3 \text{ eV}$ and $I(\text{N}_2\text{H}_3) = 7.9 \text{ eV}$, a value of $D(\text{H}-\text{N}_2\text{H}_3) = 78 \text{ kcal/mole}$ is obtained.

Unless otherwise stated, thermodynamic values were obtained from the *National Bureau of Standards Circular 500*, Washington, 1952, and *JANAF Thermochemical Tables*, The Dow Chemical Company, Midland, Michigan, up to Quarterly Supp. No. 17, March 1965.

Effect of pH and Addition of Organic Materials on Denitrification Losses from Soil

We have reported¹ that added nitrate-nitrogen was lost by denitrification during incubation of soil at moisture levels as low as 20 per cent saturation (20 per cent of the maximum water-holding capacity). For the soil used this saturation level was equivalent to $pF 4.2$, which is commonly taken as the soil moisture content at which wilting of plants occurs. This loss occurred even in the absence of added organic materials. The results do not agree with a previous report² that denitrification of added nitrate occurred only at moisture levels greater than 60 per cent saturation and then only when decomposable organic materials were added.

In view of the conflicting results it was decided to supplement the results of the previous study¹ by using the same soil and studying the effects of addition of organic materials on the extent of loss of added nitrate over the moisture range from the wilting percentage to waterlogging. In addition, pH was studied as a further variable, as this effect appears to have been studied, as yet, only under waterlogged conditions³.

Samples of the soil were adjusted to different pH levels by addition of varying amounts of calcium carbonate or aluminium chloride, followed by moist storage for 3 months with intermittent leaching. Samples having pH values of 4.7, 6.5 (the original soil) and 8.0 were selected for study. The methods used were as described previously¹, involving 12 weeks' incubation at 28°C after applying the treatments shown in Table 1. Losses of nitrogen were determined by the differences in total nitrogen content initially and at the end of incubation, with due precautions being taken to ensure complete recovery of all organic and inorganic forms of nitrogen in the samples.

Table 1. NITROGEN LOSSES IN SOIL DURING INCUBATION

	$pH 4.7$			$pH 6.5$			$pH 8.0$		
	% saturation	20	50	% saturation	20	50	% saturation	20	50
Percentage loss of applied nitrate-nitrogen									
$\text{NO}_3\text{-N}^\dagger$	2.5	4.4	56.9	10.3	21.7	82.4	2.0	24.5	71.6
" + straw [‡]	22.8	47.0	94.9	23.8	44.3	95.7	43.5	58.5	97.6
" + compost	31.2	29.7	60.8	24.4	48.0	96.1	9.5	40.2	88.9

L.S.D. ($P < 0.05$) = 5.0 per cent.

Each result is mean of duplicate treatments.

* 20 per cent, 50 per cent and 133 per cent saturation equivalent to $pF 4.2$, 2.5 and 0 (waterlogged) respectively.

† 600 p.p.m. (soil basis) as potassium nitrate dissolved in added water.

‡ Ground straw and compost added at 2 per cent w/w (dry soil basis).

The three results obtained in the previous study¹ are included in Table 1 for completeness, namely, losses at $pH 6.5$ at the three moisture levels in the absence of added organic material. In the absence of added organic material significant losses of nitrogen occurred at all pH levels under waterlogging, at $pH 6.5$ and 8.0 at 50 per cent saturation, and only at $pH 6.5$ at 20 per cent saturation. Losses due to addition of organic material (straw or compost) were increased by an average of 26 per cent at 20 per cent saturation, 28 per cent at 50 per cent saturation and 19 per cent under waterlogging. Losses of nitrogen due to addition of straw averaged 13 per cent more than those due to addition of compost, although the differences due to the two materials were consistent only at $pH 8.0$. In the presence of added organic materials nitrogen losses averaged 48, 55 and 56 per cent at $pH 4.7$, 6.5 and 8.0 respectively. With straw additions there were no consistent effects of pH on nitrogen losses at the different moisture levels. With compost additions the only consistent trend due to pH was at 20 per cent saturation, where nitrogen losses decreased with increasing pH .

In general, although greater losses of added nitrate-nitrogen occurred under waterlogging than at the two lower moisture levels, the addition of organic materials increased the extent of losses at all moisture levels, but proportionately more so at the two lower levels. The generally greater loss of nitrogen where straw than where compost was added is presumably due to the higher content of readily decomposable substances in the former material resulting in a greater supply of energy for the activity of the denitrifying organisms.

The high nitrogen losses even at $pH 4.7$ when waterlogged disagree with the results obtained by Bremner and Shaw², who found only small losses below $pH 5.0$. At any moisture level pH had no consistent effect on losses where organic materials were added. This may be related to the ability of denitrifying organisms to operate over a wide pH range³.

The results obtained indicate that losses of nitrogen by denitrification may occur in the field, where heavy applications of nitrate and organic materials are applied, even at low soil moisture levels, and that the losses may occur over a wide range of soil pH . Whether such losses would be of agronomic or economic significance in comparison with losses of nitrate by leaching can only be determined by field trials.

Absence of Diffusion Control of Reaction Rate in the Thermal Decomposition of Amorphous Polymers

ONE of the difficulties in the determination of decomposition kinetics of solids by dynamic thermogravimetry is the recognized dependence of the results on procedural variables, particularly sample size and rate of heating^{1,2}.

Fig. 1. Arrhenius plot for the thermal degradation of 'Viton A' rubber. Open symbols, 'Viton A', 100-0, mag. oxide 15-0, Diak No. 3, 3-0. Filled symbols, as follows, plus MT carbon black 25-0. (Each compound mould cured for 30 min at 150° C.) Δ , ∇ , 9-0° C min⁻¹/300 mg sample; ∇ , ∇ , 6-0/300; \square , 6-0/50; \diamond , 2-25/300

It is often postulated that slow diffusion of products from the reaction sites is a rate-controlling factor.

The decomposition of rubbers in a stream of inert gas (nitrogen) has been studied using techniques described in previous publications^{3,4}. The materials were mounted so as to permit free release of volatile decomposition products from the sample to the inert gas stream.

In contrast to published results of decomposition studies on crystalline solids, the overall kinetics of pyrolysis of amorphous polymers in the rubbery state do not appear to be influenced seriously by sample size or by heating rate within the ranges of these variables covered in the present study.

The rubbers examined have been ethylene-propylene terpolymers ('Nordel', 'Royalene'), chlorosulphonated polyethylenes ('Hypalon') and vinylidene fluoride-hexafluoropropylene copolymers ('Viton'). Heating rates have been varied between 2° and 10° C min⁻¹ and sample sizes from 20 to 300 mg and, in one experiment, a 1,000-mg single piece of 'EPT' rubber. Fig. 1 gives typical kinetic data for the main stage of decomposition of vulcanized 'Viton A'.

Kinetics of Formation of the Monoacetylacetonato-Iron (III) Complex

Few kinetic investigations on the formation of complexes with β -diketones are found in the literature. Taft and Cook examined the reaction of thenoyltrifluoroacetone with various metal ions and in particular that with Fe(III).

They found the rate-determining step is the reaction of Fe(III) with the enolate anion¹. Celiano and Gentile have investigated the kinetics of the reaction of acetylacetonone, benzoylacetone and its derivatives with Cu(II), and indicated that the rate-determining step is the reaction of Cu(II) with the enol form of the β -diketone and with its enolate anion². In an attempt to evaluate the two types of mechanisms proposed, we have examined the reaction of acetylacetonone, benzoylacetone, trifluoroacetylacetone and thenoyltrifluoroacetone with Fe(III)³. The behaviour is very similar in all cases and under our conditions the product is the mono-chelated complex, Fe(AA)²⁺. The results of experiments on the acetylacetonone/Fe(III) reaction are reported here.

The complex Fe(aca)²⁺ was reported to be formed from acetylacetonone (Haca) reacting with Fe(III) at pH=1.65–2.65 (ref. 4). To avoid the formation of Fe(aca)₂⁺ we have examined this reaction under conditions where the Fe(III)/Haca ratio was maintained at between 100/4 and 300/4, and high acid concentration (0.01–0.1 M). The kinetics were observed by a spectrophotometric method using the absorption band at 485 m μ which is λ_{\max} for Fe(aca)²⁺ (ref. 4). Good linear first-order plots were obtained. Some typical results are shown in Table 1.

Table 1

k_{obs} vs (Haca) (Haca)	$[\text{Fe}] = 2 \times 10^{-2} \text{ M}$, $[\text{H}^+] = 0.1 \text{ M}$, $\mu = 0.5$ $[\text{Fe}]/[\text{Haca}]$	$k_{\text{obs}} (\text{sec}^{-1}) \times 10^2$
1.0×10^{-4}	200	1.90
2.0×10^{-4}	100	1.93
3.0×10^{-4}	66.7	1.89
4.0×10^{-4}	50	1.89
5.0×10^{-4}	20	1.88

By varying the amounts of excess Fe(III) and acid concentration we have found that

$$k_{\text{obs}} = k_1 - \left[k_2 + k_3 \frac{1}{[\text{H}^+]} \right] [\text{Fe}]$$

and so the overall rate expression becomes

$$\text{Rate} = k_1[\text{Haca}] - k_2[\text{Haca}][\text{Fe}] + k_3[\text{Haca}] \frac{[\text{Fe}]}{[\text{H}^+]}$$

The values of the k 's at 25° C and $\mu = 0.5$ are:

$$\begin{aligned} k_1 &= 1.22 \times 10^{-2} (\text{sec}^{-1}) \\ k_2 &= 0.26 (\text{sec}^{-1}\text{M}^{-1}) \\ k_3 &= 0.81 \times 10^{-2} (\text{sec}^{-1}) \end{aligned}$$

To interpret this equation we propose that three simultaneous reactions are operating,

If this scheme is correct the first term corresponds to the rate of acid dissociation of the β -diketone: the k_1 value corrected to zero ionic strength ($1.40 \times 10^{-2} \text{ sec}^{-1}$) agrees closely with that reported for such dissociations ($1.67 \times 10^{-2} \text{ sec}^{-1}$ (ref. 5a), $1.32 \times 10^{-2} \text{ sec}^{-1}$ (ref. 5b), $1.40 \times 10^{-2} \text{ sec}^{-1}$ (ref. 5c)).

The reactions (B) and (C) are reminiscent of the reactions of Fe(III) with anions such as SCN⁻, Cl⁻, etc.⁶. Negligible effects of ionic strength on k_2 and k_3 are observed.

The temperature variation of the rate constant has been measured, and the ΔH^\ddagger and ΔS^\ddagger values calculated from the plots of $\log k/T$ versus $1/T$ are shown in Table 2.

Table 2. TEMPERATURE DEPENDENCE OF k_1 , k_2 , k_3

	ΔH^\ddagger	ΔS^\ddagger
k_1	11.9 cal	-27.4 cal deg ⁻¹
k_2	11.7 "	-16.9 "
k_3	14.5 "	-15.1 "

This reaction has been used as an indicator for observing the solvolysis of $M(\text{aca})_3\text{FeCl}_4$, where $M = \text{Si, Ge}$ (ref. 3). These compounds have been shown to be 1:1 electrolytes

with octahedrally co-ordinated cations⁷. The solvolytic behaviour for $\text{Si}(\text{aca})_3\text{FeCl}_4$ and $\text{Si}(\text{aca})_3\text{HCl}_2$ is very similar. The rates are shown in Table 3.

Table 3. SOLVOLYSIS OF $M(\text{aca})_3^+$

	pH	k_{obs} (sec^{-1}) $\times 10^4$		Ref.
		25° C	35° C	
$\text{Si}(\text{aca})_3\text{FeCl}_4$	< 6	2.8	7.7	(3)
$\text{Ge}(\text{aca})_3\text{FeCl}_4$	< 6	2.7	6.4	(3)
$\text{Si}(\text{aca})_3\text{HCl}_2$	< 6	2.7	—	(8)

It is interesting that the solvolytic reactivity of the germanium compound is closely similar to that of silicon. This contrasts with the situation in the four co-ordinated halides in which Ge and Si can show wide differences⁹.

Heterogeneity of Titan Yellow demonstrated by Thin-layer Chromatography

SINCE the first observations by Mikkelsen and Toth¹ it has been well established that the reaction between magnesium ions and titan yellow (the sodium salt of methylbenzothiazole (1,3)-4,4'-diazamino benzene (2,2')-disulphonic acid) can be extremely variable due to differences in the composition of the dye. In an attempt to overcome difficulties in the determination of magnesium in plant samples due to such variations Bradfield² recommended a technique for assessing the sensitivity of the dye and later reported the presence of a component which was intensely fluorescent³.

Although atomic absorption spectroscopy has to some extent supplanted the use of titan yellow for magnesium determinations there are many investigators who still rely on this procedure, and during some recent work in this laboratory difficulties were encountered with the determination of plant and soil magnesium employing the dye by published methods^{2,4}. Examination by thin-layer chromatography of some fourteen samples of titan yellow from three manufacturers showed them all to be much more heterogeneous than has previously been described.

Figs. 1 and 2 show a thin-layer chromatogram of a selection of the titan yellows examined from the three sources. The separation was effected on silica gel/alumina (6 g : 12 g in 36 ml. of 5 : 1 water/ethanol mixture) and developed for 6 h with *n*-butanol equilibrated with 1.5 N NH_4OH . The plate was spotted with 20 μl . of a solution containing 5 mg/ml. of dye and was photographed in ultra-violet light using a Kodak Plus X Pan film. The yellow component which is magnesium reactive had an R_F value of 0.25–0.40 with a mean of 0.32 and was the major fraction in samples B, E and H. Samples A and H 22, however, contained very little Mg^{++} -reactive material, but large amounts of yellow non-reactive substances were present which remained at the base line or moved much more slowly than the Mg^{++} -reactive dye. Sample M appeared to be a mixture containing many unreactive components but was also fairly rich in the active fraction. In addition to the multiple yellow fractions, all the samples of titan yellow which were examined contained a varying number of spots which exhibited brilliant blue and yellow-green fluorescence when viewed in ultra-violet light and

Fig. 1. Thin-layer chromatogram of titan yellows on silica gel/alumina viewed in ultra-violet light

Fig. 2. Key to chromatogram shown in Fig. 1

which tended to travel much faster than the yellow components, although fluorescent spots and bands were seen in some samples interspersed with the main yellow spots. Evidence of the blue fluorescent substances was particularly striking in samples A, H and H 22. In H two large mushroom-shaped components were seen. These particular fluorescent spots were initially invisible to the eye in daylight but after several days' exposure became brown, presumably due to the formation of an oxidation product.

Although colour transparencies demonstrated the complexity of the chromatogram rather better than can be seen in Fig. 1, many more spots were seen in ultra-violet light with the naked eye.

Use has been made of these observations in selecting a titan yellow for magnesium determinations. Samples A, H, H 22 and M were found to be unsuitable for analytical procedures. Further work has now been carried out to establish the presence in all the samples of dye, of a fraction which gives a consistent reaction with magnesium, and the optimum conditions required. It has been possible to develop methods for the determination of total plant magnesium and available magnesium in soil extracts, the results of which show close agreement with those obtained by atomic absorption spectroscopy.

Charge Transfer Properties of *dl*-Thioctic Acid and Other Disulphides

THE ability of organic sulphur compounds to act as donors with electron acceptor molecules is well established. As far as disulphides are concerned, previous studies have been limited to simple aliphatic compounds with iodine as the acceptor¹. In these systems, the charge transfer (CT) band appears between the disulphide absorption and the blue-shifted iodine absorption, and its position appears to be little affected by changing the alkyl groups. We wish to report that alkyl aryl and cyclic disulphides form 1:1 complexes in solution with tetracyanoethylene (TCNE), which show well-separated CT bands in the visible region. Further, the position of these bands clearly reflects steric and electronic factors in the disulphide molecule.

The complexes are readily generated by mixing rigorously purified solutions of the donor and acceptor. Special care must be taken to remove thiols, which are the major impurities in disulphides, since these react with TCNE. Table 1 lists some representative spectral data; several sulphides are included for comparison. It is apparent that (1) simple alkyl disulphides show a progressive decrease in CT transition energy with increasing chain length; (2) branched chain complexes absorb at longer wave-lengths than the corresponding straight chain complexes; (3) for disulphides, ring closure has a larger effect on the CT transition than elongation of the alkyl chain, while the opposite is the case for sulphides. The complexes have low formation constants (K_c , l./mole) and molar extinction coefficients (ϵ). In dichloromethane at 25° typical values are: methyl disulphide $K_c=0.16$, $\epsilon=2,100$; *tert*-butyl disulphide $K_c=0.36$, $\epsilon=4,500$; *dl*-thioctic acid $K_c=1.22$, $\epsilon=6,500$. The corresponding enthalpies of formation are -0.4 , -1.5 , and -7.2 kcal/mole. Based on the photoionization value of 8.46 eV for methyl disulphide², we estimate the ionization potentials of *tert*-butyl disulphide and *dl*-thioctic acid to be 7.78 and 7.53 eV, respectively. The general trend of these data may be rationalized in terms of the increased inductive (electron-releasing)-effect of the larger alkyl groups, and the decrease in the dihedral angle between the adjacent sulphur 3- $p\pi$ orbitals which accompanies an increase in the size of the group or ring closure³. Both factors would be expected to enhance the stability of the complex.

Apart from the CT band, the complexes show absorption arising from the complexed components. Resolution of the spectrum of a TCNE-*dl*-thioctic acid solution (Fig. 1) reveals that the band associated with the —S—S— group

Fig. 1. Resolution of spectrum of dichloromethane solution, 2.786×10^{-2} M in *dl*-thioctic acid and 4.726×10^{-4} M in TCNE. A, Total absorption; B, free —S—S—; C, free TCNE; D, complexed —S—S—

of the complexed acid (curve D) is shifted to shorter wave-lengths by about 23 mμ, relative to that of the free acid (curve B). With TCNE-ethyl disulphide the component absorptions overlap, and the complexed —S—S— band cannot be clearly separated from the complexed TCNE band. The shift is estimated to be 0–6 mμ to longer wave-lengths. For ethyl disulphide, complexation can be envisaged to increase the dihedral angle¹ with consequent lowering of the transition energy. No such structural adaptation occurs with the rigid cyclic disulphide. Consideration of the orientation of the donor orbitals indicates that the two complexes would differ in geometry, particularly with respect to symmetry in the donor-acceptor bond region, and that consequently the perturbation of these orbitals would be different. A forthcoming publication will elaborate this concept.

Homogeneous Hydrogenation and Hydroformylation using Ruthenium Complexes

WE have shown¹ that the rhodium (I) complex, $\text{RhCl}(\text{PPh}_3)_3$, is an extremely efficient catalyst for the homogeneous hydrogenation of olefins and acetylenes at 25° C and at < 1 atmosphere pressure in benzene solutions. This activity is due, in part, to the dissociation of the complex in solution to give a solvated species $\text{RhCl}(\text{PPh}_3)_2\text{S}$, which has a vacant co-ordination site additional to the solvent-occupied axial positions.

We now find that the ruthenium (II) complexes, $\text{RuCl}_2(\text{PPh}_3)_4$ and $\text{RuCl}_2(\text{PPh}_3)_3$, prepared respectively by the interaction of cold and refluxing methanol solutions of hydrated ruthenium trichloride with excess triphenylphosphine, dissociate in benzene solutions². Molecular-weight investigations show that the dissociation is:

Since the solutions are sensitive to air, the colour changes reported³ for solutions of $\text{RuCl}_2(\text{PPh}_3)_3$ are probably attributable to oxidation.

Table 1. CHARGE TRANSFER MAXIMA OF TCNE-SULPHUR COMPOUND COMPLEXES IN DICHLOROMETHANE SOLUTION

Donor	λ_{max} (mμ)	Donor	λ_{max} (mμ)
Alkyl, aryl disulphides:		Cyclic disulphides:	
Methyl	425	Tetramethylene	535
Ethyl	450	Trimethylene	575
<i>n</i> -Propyl	453	<i>dl</i> -Thioctic acid	583
<i>n</i> -Butyl	460	Sulphides:	
<i>iso</i> -Propyl	465	Ethyl	505
<i>tert</i> -Butyl	530	<i>n</i> -Butyl	530
Cyclohexyl	525	Phenyl	580
Phenyl	515	Pentamethylene	495
Mesityl	430	Tetramethylene	515

Both olefines and acetylenes such as hept-1-ene and hex-1-yne are rapidly hydrogenated at 25° and at 1 atm. by the ruthenium complexes at about 10^{-3} M concentration in benzene-ethanol (1:1) solution. In contrast to the rhodium system, ethanol plays an intimate part in the hydrogenation mechanism; in absence of such a co-solvent, hydrogenation is exceedingly slow. Deuterium investigations, coupled with mass spectroscopic and nuclear magnetic resonance examinations show that: (a) mixed hydro-deutero paraffins are obtained using D_2 ; (b) in the absence of olefine, rapid exchange between the hydroxyl group of ethanol and D_2 occurs. Treatment of concentrated solutions of the complex in ethanol-benzene with H_2 gives a hydrido complex $RuClH(PPh_3)_3$, identified by analysis, infra-red ($\nu_{Ru-H} \sim 2,000\text{ cm}^{-1}$) and nuclear magnetic resonance ($\tau_H = 28.6$) spectroscopy, so that, as before¹, a hydrido species is confirmed as a hydrogenation intermediate.

The rhodium complex $RhCl(PPh_3)_3$ with CO rapidly gives $RhClCO(PPh_3)_2$ and the latter is an effective hydroformylation catalyst for olefines and acetylenes^{1,4}. Although the tetrakis(triphenylphosphine) ruthenium complex gives only low yields of aldehyde from, for example, hept-1-ene (due to the formation of an insoluble carbonyl species $RuCl_2(CO)_2(PPh_3)_2$) the more-soluble complex $RuCl_2(PPh_3)_2CH_3OH$ gives higher yields. However, the most effective ruthenium complex is $Ru(CO)_2(PPh_3)_2$ (ref. 5), which in benzene solution at about 10^{-2} M concentration under mild conditions, for example, 100 atm. total pressure of CO and H_2 (1:1) and 100° C, gives more than 80 per cent yields of hexaldehydes from pent-1-ene, in about 15 h. This appears to be the first case where a well-defined ruthenium complex has been shown to be a hydroformylation catalyst. There have been patents claiming the use of solid catalysts⁶ and a very general claim⁷ covering the use of transition metals in the presence of phosphines, phosphites, etc., but no examples using ruthenium or rhodium were quoted, nor were any stoichiometric complexes of these elements defined.

BIOCHEMISTRY

Lysozymes characterized in Duck Egg-white: Isolation of a Histidine-less Lysozyme

CONTINUING our work on lysozymes from different origins (human; avian egg-white)¹, we have purified, analysed and compared different lysozymes isolated from the duck egg-white.

One l. of duck egg-white was homogenized with 4 l. of water; the pH was adjusted to 4.5 and the solution was mixed for 4 h with 200 ml. of 'Amberlite CG-50 (Type II)' buffered at pH 6.5 with a 0.2 M phosphate buffer. The purification was continued following the procedure of Jollès *et al.*²: elution from 'Amberlite' with a 0.8 M phosphate buffer of pH 6.5; chromatography on CM-cellulose, filtration on 'Sephadex G-25' with water as eluent, and lyophilization. Yield at this stage was about 500 mg of lysozyme (expressed as hen's egg-white lysozyme). It was possible to purify this material further by ion-

exchange chromatography on 'Amberlite CG-50 (Type II)' columns buffered with a 0.2 M phosphate buffer of pH 7.56. Fig. 1 shows that three different lytic enzymes can be obtained in this way, containing respectively 25, 25 and 50 per cent of the initial activity. However, peak No. 3 was not eluted during the ion-exchange chromatography but only with a 0.8 M buffer solution. This lysozyme was desalted again on 'Sephadex G-25' and submitted to a new chromatography in slightly different conditions as indicated in Fig. 2. The purity of these three lysozymes obtained in a chromatographically pure state had been tested again by electrophoresis on 'Cellolog' strips (Chemetron, Milan) (0.1 M acetate buffer of pH 4.5; 110 V; 1.5 h) (Fig. 3). The third active fraction had also been purified by a different procedure by Fujio *et al.*³, but no further analytical investigations were reported by these authors.

Amino-acid analyses were performed after total hydrolyses (6 N hydrochloric acid; 110°; sealed tube) of 18 and 40 h with a Technicon 'AutoAnalyzer'. Cystine was determined after performic acid oxidation and tryptophan following the procedure of Spies and Chambers⁴. As can be seen from Table 1, peak 1 on one side, peaks 2 and 3 on the other, contain analytically quite different substances; the lysozymes from peaks 2 and 3 contain no histidine; it is the first lysozyme devoid of this amino-acid, and this observation seems important, as many investigations were

Fig. 1. Ion-exchange chromatography on 'Amberlite CG-50' (67 cm x 1.5 cm) of duck egg-white lysozymes No. 1 and No. 2 (initial activity: 100 mg).

Fig. 2. Ion-exchange chromatography on 'Amberlite CG-50' (67 cm x 1 cm) of duck egg-white lysozyme No. 3 (39 mg).

Fig. 3. Electrophoresis on 'Cellolog' strips of duck egg-white lysozymes. a, peak No. 1; b, peak No. 2; c, peak No. 3; d, peaks No. 1 + No. 2 + No. 3 as contained in the material obtained after chromatography on CM-cellulose

devoted to the possible part played by histidine in an eventual active centre⁸⁻⁹. The different chromatographic behaviour of the enzymes contained in peaks 2 and 3 may be due to a different amide-group content.

Digestion experiments with carboxypeptidase allowed to establish that leucine is the C-terminal amino-acid of the duck egg-white lysozyme contained in peak 3.

The new lytic enzymes possess the six properties which allow them to be ranged among the lysozymes^{1,10}: they are basic proteins of low molecular weight, stable at acidic pH even at 100° for 1-2 min, unstable at alkaline

pH, active against suspensions of *M. lysodeikticus* and liberating, by their action on an appropriate substrate, substances which can be detected by specific reagents for amino sugars.

Table 2 summarizes some results obtained during our comparative examination of duck lysozymes, two other birds' egg-white and three human lysozymes^{1,11-14}.

This investigation was supported in part by grant FG-Fr-106 from the U.S. Department of Agriculture.

Evidence discriminating between the Chemical and the Chemiosmotic Mechanisms of Electron Transport Phosphorylation

WE have recently reported that when suspensions of intact rat liver mitochondria hydrolyse ATP, oxidize succinate, or oxidize β -hydroxybutyrate, protons are translocated (written $\rightarrow H^+$) outwards through the mitochondrial membrane with stoichiometries closely approximating to $\rightarrow H^+/P=2$, $\rightarrow H^+/O=4$ and $\rightarrow H^+/O=6$ respectively¹. These observations are in close accord with the requirements of the chemiosmotic hypothesis, according to which electron transport and phosphorylation are coupled by the proton current flowing cyclically through the respiratory chain and reversible ATPase systems across the cristae membrane²; but they could also be explained according to the chemical hypothesis, by invoking a proton pump driven by hydrolysis of $X \sim I$, either directly, or via the 'W complex' suggested by Lardy, Connelly and Johnson³. We have, therefore, sought more crucial experimental tests of the alternative hypotheses.

The fact that fragments of cristae membrane (sonic particles), segregated from sonically disintegrated mitochondria, will catalyse oxidative phosphorylation⁴, energy-linked transhydrogenation⁵, and other reversed electron-transfer reactions⁶ appears to favour the chemical hypothesis, because: (a) the system still works chemically though apparently disorganized morphologically; (b) the membraneous (or other) barrier confining soluble enzymes, co-enzymes and substrates within intact mitochondria, and preventing intermediates such as NAD and NADP from participating in 'energy-linked' electron transport from outside, have apparently disappeared from the sonic particles. It seemed to us that in view of the facts concerning sonic particles, the survival of the chemiosmotic hypothesis would be dependent on the following two rather exacting criteria: (1) the limiting membrane of the sonic particles must be osmotically functional; (2) the membrane of the particles must be inside out so that the side normally accessible only to internal NAD, ATP, substrates, etc., would be directly accessible to NAD, ATP, substrates, etc., in the suspension medium. We have

Table 1. AMINO-ACID COMPOSITION OF DUCK EGG-WHITE LYSOZYMES (RESIDUE/MOLE AFTER 18 h AND 40 h TOTAL HYDROLYSIS)

Amino-acid	Peak 1		Peak 2		Peak 3	
	18 h	40 h	18 h	40 h	18 h	40 h

(milk, saliva, placenta, etc.)	95 \pm 5*	6.98	0.20	122 \pm 5

* A small active peak (≤ 10 per cent of total activity) is eluted before the main peak; it contains probably the same enzyme partially deaminated.
n.d., not determined.

examined these criteria experimentally in sonic particles⁷ from rat liver and from beef heart mitochondria, using techniques similar to those reported on intact rat liver mitochondria¹; these preliminary investigations can be summarized as follows:

(1) The sonic particles behave as a two-phase system when titrated with acid or alkali, and the rate of acid-base equilibration between the internal and external phases is of the same order of magnitude as the rate observed in intact mitochondria.

(2) When the sonic particles hydrolyse ATP, oxidize succinate, or oxidize NADH, protons are translocated inwards through the membrane which separates the inner phase of the particles from the suspension medium, the stoichiometries so far obtained, under conditions that are probably sub-optimal, being respectively $\rightarrow H^+/P=0.53$, $\rightarrow H^+/O=0.83$, and $\rightarrow H^+/O=1.29$. Proton translocation during ATP hydrolysis could be inhibited by oligomycin but not by antimycin A or rotenone, whereas proton translocation during succinate and NADH oxidation was stimulated (about 25 per cent) by oligomycin and inhibited by antimycin A. Rotenone inhibited the NADH-linked proton translocation, but not the succinate-linked proton translocation.

We conclude that the sonic particles possess an osmotically functional membrane, and that, as suggested by Lee and Ernster⁸ in connexion with the effects of Mg^{++} on reversed electron transport, the cristae membrane is effectively turned inside out during sonic disintegration of mitochondria.

Our observations imply that the facts relating to the sonic particles can no longer be regarded as favouring the chemical hypothesis of electron transport phosphorylation. On the other hand, the proponents of the chemical hypothesis could explain the proton translocation in sonic particles, just as in intact mitochondria, by invoking a hypothetical membrane-located proton pump driven by hydrolysis of $X \sim I$.

According to the chemiosmotic hypothesis, protons are translocated across the membrane during oxido-reduction because hydrogen atoms pass across one way via hydrogen carriers and electrons pass across the other way via electron carriers in the membrane-located respiratory chain²; and it follows that the direction of translocation of protons should reverse if electron and hydrogen atom flow reverses. According to the explanation of proton translocation in terms of the chemical hypothesis, however, protons would be pumped through the membrane when forward electron transport synthesized $X \sim I$ (via $C_1 \sim I$, $C_2 \sim I$, etc.); but although, according to this view, the reversal of electron transport would consume $X \sim I$, it would not reverse the flow of protons through the $X \sim I$ -hydrolysing proton pump unless either $X \sim I$ could exist in minus quantities, or the proton pump could become possessed by a Maxwell demon, reversing the thermodynamically natural processes and synthesizing $X \sim I$ from XH , IOH , and H_2O . It is thus evident that the relationship between the change of direction of electron flow and the direction of proton translocation should be diagnostic of the coupling mechanism.

We have observed, by techniques similar to those recently described¹, that the flow of electrons in the reverse, or 'energy-consuming', direction through the transhydrogenase system of sonic particles from beef heart mitochondria (prepared by a method similar to that of Löw and Vallin⁷) causes the outward translocation of protons through the membrane, whereas the protons are translocated inwards during forward electron transport and ATP hydrolysis by these particles. Our present techniques give an observed $\rightarrow H^+/2e$ stoichiometry of 0.21, which, like the forward stoichiometries, can be assumed to be sub-optimal. Further, we have found that reversed electron transport through the succinate oxidase segment of the respiratory chain of beef heart mitochondria between fumarate and the component reacting with

artificial hydrogen donors on the oxygen side of the antimycin A-sensitive site is accompanied by reversed proton translocation.

These observations, which will be reported in detail elsewhere, appear to provide the first crucial evidence against the chemical hypothesis of electron transport phosphorylation. They also provide the most powerful evidence so far obtained in support of the chemiosmotic hypothesis.

Enzymatic Formation of β -Cyanoalanine from Cyanide by *Escherichia coli* Extracts

BLUMENTHAL-GOLDSCHMIDT *et al.*¹ demonstrated that carbon-14 atoms from ^{14}C -labelled HCN supplied to several types of seedling became incorporated almost exclusively into the amide-C of asparagine. Subsequent work^{2,3} indicated that these authors had selected, somewhat fortuitously, mainly asparagine-synthesizing species rather than others which incorporated ^{14}C -cyanide almost entirely into a dipeptide, γ -glutamyl- β -cyanoalanine. This γ -glutamyl peptide is known as a normal constituent only of certain *Vicia* species^{4,5}; its formation in other species is apparently dependent on an exogenous supply of cyanide.

The time-course of ^{14}C -cyanide incorporation by *Chlorella* cultures indicated that β -cyanoalanine was the primary labelled product³; this is afterwards converted either into asparagine by the action of a hydrolysing nitrilase or into γ -glutamyl- β -cyanoalanine by a γ -glutamyl transferring enzyme. These alternative pathways from β -cyanoalanine adequately explain the labelling patterns that develop after ^{14}C -cyanide feeding to a wide variety of species including cultures of *E. coli*, which accumulate radioactivity mainly in asparagine.

Nigam and Ressler⁶ suggested that β -cyanoalanine was formed by a reaction between serine and cyanide, after observing that cyanide stimulated the incorporation of radioactivity into γ -glutamyl- β -cyanoalanine in intact *V. sativa* seedlings that had received ^{14}C -serine. The present communication describes some properties of an enzyme, present in *E. coli* extracts, which catalyses β -cyanoalanine formation from serine and cyanide, while the accompanying letter⁷ presents similar data for an enzyme from *Lotus* seedlings. Since β -cyanoalanine and γ -glutamyl- β -cyanoalanine are not encountered generally in plants, we consider it likely that the catalysis of β -cyanoalanine formation represents a non-specific activity of an enzyme that plays some other indispensable part in living cells. Such an enzyme could be serine sulphydrase⁸, which promotes cysteine biosynthesis from serine and sulphide.

Enzyme preparations were obtained from cells of *E. coli* (strain K12) growing logarithmically on a glucose-mineral salts medium at 30° C. Heavy suspensions of washed cells were disintegrated ultrasonically and the cell-free supernatant obtained after centrifuging at 40,000g for 30 min was dialysed overnight at 1° C against 0.1 M K_2HPO_4 . This dialysed extract (containing 25–50 mg protein/ml.) was used as a source of enzyme. Activities

were measured by following the incorporation of radioactivity into β -cyanoalanine in systems normally containing L-(3- ^{14}C) serine as the labelled substrate. Unlabelled β -cyanoalanine was added to the assay system in amounts sufficient to reduce to negligible proportions the further conversion of the labelled β -cyanoalanine produced into asparagine.

The standard assay mixture had the following composition: serine, 0.5 $\mu\text{c.}$, 11 $\mu\text{g.}$; KCN, 500 $\mu\text{g.}$; β -cyanoalanine, 25 $\mu\text{g.}$; enzyme preparation, 0.1 ml.; total volume, 0.12 ml. Mixtures were incubated at 30° C for various periods and reaction was stopped by the addition of two volumes of ethanol. After the removal of precipitated protein, the supernatant was applied to two-dimensional chromatograms (developed in phenol-ammonia followed by butan-1-ol-acetic acid-water) to separate β -cyanoalanine from other ^{14}C -labelled substances before determination of radioactivity by Geiger scanning. Under these conditions, a pH of 9.0 was optimal for β -cyanoalanine formation. The high concentrations of cyanide present in the standard assay mixture did not fully saturate the enzyme, since a further small increase of rate was observed with amounts of KCN up to 800 $\mu\text{g.}$ (that is, a concentration of about 0.1 M). The K_m value calculated for KCN was about 4×10^{-2} M; this value corresponded to a K_m value of about 1.3×10^{-2} M for cyanide ion.

The dependence of reaction rate on serine concentration was investigated using potassium ^{14}C -cyanide (5 $\mu\text{c.}$, 500 $\mu\text{g.}$) as substrate: serine concentrations in the range 10^{-4} – 7×10^{-2} M were used. The reaction attained its limiting velocity at a serine concentration of 4×10^{-2} M and a K_m value of 8×10^{-3} M was calculated. The *E. coli* enzyme (unlike that from *Lotus* seedling⁷) exhibited a partial dependence on ATP. Fig. 1 illustrates the stimulation of β -cyanoalanine formation by ATP: a four-fold increase of reaction rate was observed in the presence of ATP concentrations greater than 0.01 M. Schlossmann and Lynen⁸ state that serine sulphydrase is ATP-dependent.

The effect of other additions to the standard assay mixture is illustrated by the data in Table 1. The presence of Mg^{2+} or *O*-phosphorylserine resulted in a striking inhibition of radioactive β -cyanoalanine formation (compare with the findings using the *Lotus* enzyme). Since ATP stimulated the reaction, phosphorylserine seemed at first to be a logical intermediate in β -cyanoalanine formation. A biogenetic mechanism of this type would be associated with the incorporation of radioactivity into the phosphoryl derivative, but in practice phosphorylserine remained unlabelled in our experiments. However, it was hydrolysed rapidly, thereby reducing the specific activity

Table 1. SHOWING THE COMPARATIVE RATES OF β -CYANOALANINE FORMATION Determined after the addition of various substances to the standard assay mixture containing L-(3- ^{14}C) serine, 0.5 $\mu\text{c.}$, 11 $\mu\text{g.}$; KCN, 500 $\mu\text{g.}$; β -cyanoalanine, 25 $\mu\text{g.}$; enzyme preparation, 0.1 ml., in a final volume of 0.12 ml

	Per cent of control rate
Standard assay mixture (control)	100
- Cyanide	< 0.1
+ Mg^{2+} (30 mM)	22
+ <i>O</i> -phosphorylserine (8 mM)	26
+ L-Alanine (16 mM)	109
+ L-Threonine (12 mM)	103
+ ATP (10 mM)	434
+ L-Cysteine (4 mM)	5-10
+ Sodium sulphide (2 mM)	4
+ Sodium sulphide (0.5 mM)	~ 80

of the ^{14}C -serine in the assay mixture and so causing an apparent reduction in reaction rate. Neither alanine nor threonine affected the rate of β -cyanoalanine production and so they did not compete as alternative substrates for the active sites of the enzyme.

The addition of cysteine caused a most pronounced reduction in the conversion of ^{14}C -serine into β -cyanoalanine. This observation suggested that cysteine also may act as a substrate for enzymatic formation of β -cyanoalanine. Confirmation was obtained in an experiment in which labelled β -cyanoalanine was formed from ^{14}C -cyanide (5 $\mu\text{c.}$, 500 $\mu\text{g.}$) and cysteine; the K_m value determined for cysteine was approximately 5×10^{-3} M. The presence of sulphide ion also resulted in a striking reduction of β -cyanoalanine formation. Under these conditions radioactivity was introduced into a sulphur-containing amino-acid (presumably cysteine) because ^{14}C -label was detected in cysteic acid present in mixtures that had been oxidized at the end of the reaction period.

If serine sulphydrase, which catalyses reaction (1), can utilize a wider range of substrates than has been appreciated so far, then our observations can be explained in terms of the non-specific action of this enzyme in catalysing reactions (2) and (3).

Most of the experiments described have been aimed at examining reaction (2), but those involving cysteine suggested that this amino-acid can undergo a facile reaction with cyanide as in reaction (3).

Enzymatic Formation of β -Cyanoalanine from Cyanide

IN 1963 Blumenthal-Goldschmidt *et al.*¹ demonstrated the incorporation of ^{14}C -labelled hydrogen cyanide into asparagine by seedlings of a number of plant species. They showed that the label from H^{14}CN almost exclusively entered the amide carbon of asparagine and obtained preliminary evidence that the other three carbon atoms might be provided by serine or a closely related metabolite. These findings have been confirmed and extended by Tschiersch^{2,3}, Ressler *et al.*^{4,5} and by Fowden and Bell⁶.

Fig. 1. Effect of ATP formation in the standard assay mixture containing *E. coli* enzyme

The available evidence suggests that HCN reacts with serine to form β -cyanoalanine which then, depending on the plant species used, can either be hydrolysed to asparagine or can be converted into a peptide, γ -glutamyl- β -cyanoalanine. The two latter reactions have been demonstrated in extracts of seedlings⁶, but enzymatic evidence for the first reactions has so far not been reported.

The enzymatic formation of β -cyanoalanine has now been observed by incubating homogenates of *Lotus tenuis* seedlings with $H^{14}CN$ and L-serine. The reaction was followed by measuring the incorporation of ^{14}C from $K^{14}CN$ into β -cyanoalanine. Differential centrifugation of homogenates prepared in the presence of 0.4 M sucrose showed the enzyme to be present mainly in the mitochondria, with some activity in the supernatant solution obtained at 105,000g. The enzyme could be rendered soluble by preparing acetone powders either of whole seedlings or the mitochondria. With $H^{14}CN$ and serine as substrates, the activity has been precipitated from extracts of acetone powders of whole seedlings between 35 and 50 per cent saturation with ammonium sulphate at pH 7.3 and subjected to a heat treatment (10 min at 50°). This preliminary purification gave a five-fold increase in the specific activity.

Both ^{14}C -labelled cyanide and ^{14}C -labelled serine have been used as substrates. On incubation with $K^{14}CN$, 96 per cent of the radioactivity of β -cyanoalanine was found to be located in C-4, while with L-serine- $U^{14}C$, C-4 had 1 per cent, C-1 37 per cent and the two centre carbons had 62 per cent of the radioactivity of cyanoalanine. As shown in Table 1, however, the rate of β -cyanoalanine formation from $H^{14}CN$ and cysteine is about 50 times as rapid as from $H^{14}CN$ and serine. Under identical conditions, for example, 1.80 μM of cyanoalanine were formed without added serine, 2.75 μM on addition of 2.5×10^{-3} M L-serine but 98.0 μM in the presence of 2.5×10^{-3} M L-cysteine. The fact that cysteine apparently can serve as a source of carbon atoms 1, 2 and 3 of β -cyanoalanine was confirmed by the use of cysteine- $1^{14}C$, which gave rise to ^{14}C -labelled β -cyanoalanine carrying most of its label in the carboxyl group. The formation of β -cyanoalanine in the intact plant thus may involve cysteine rather than serine as a 3-carbon precursor, a possibility which so far seemingly has not been investigated by feeding experiments.

Table 1. EFFECT OF POSSIBLE CO-FACTORS AND INHIBITORS ON ENZYMATIC FORMATION OF β -CYANOALANINE

Reaction mixture: enzyme 1.0 ml., potassium phosphate pH 7.3, 70 μ moles, L-serine, 5 μ moles; $K^{14}CN$, 5 μ c. = 0.5 μ moles; final volume 2.0 ml. Incubations were run for 2 h at 33°

	μ moles Cyanoalanine formed	Per cent of controls
Control	2.75	100
- Serine	1.80	66
- Serine + 2.5×10^{-3} serine phosphate	1.96	71
- Serine + 2.5×10^{-3} M cysteine	98.0	3,560
+ 5×10^{-4} M $MgCl_2$	2.70	98
+ 2.5×10^{-4} M pyridoxal phosphate	5.88	213
+ 10^{-3} M ATP	1.93	70
+ 10^{-2} M EDTA	2.68	98
+ 10^{-3} M, α, α' -dipyridyl	0.24	9
+ 10^{-2} M semicarbazide	1.34	49
+ 10^{-2} M hydroxylamine	0.36	13
+ 10^{-2} M isoniazid	4.50	164
+ 10^{-2} M iodacetamide	0.71	26
+ 10^{-3} M <i>p</i> -chloromercuribenzoate	0.36	13
+ 10^{-2} M $HgCl_2$	0.62	23

The reaction leading to β -cyanoalanine had a pH optimum at pH 9. The K_m value for KCN was found to be pH dependent; approximate values were estimated (using serine as a second substrate) to be 4×10^{-4} M at pH 7.3 and 1.5×10^{-5} M at pH 9.0. This shows that CN^- and not HCN is the true substrate of the reaction and the true K_m value for CN^- can be estimated to be in the order of 5×10^{-6} M. For cysteine a K_m of 9×10^{-5} was determined. No K_m value for serine could be obtained because the response of cyanoalanine formation to changes in the serine concentration was too low to give significant data.

The results of some experiments with possible co-factors and inhibitors are also shown in Table 1. The reaction does not require ATP, and serine phosphate cannot replace serine or cysteine as substrates. The enzyme may use pyridoxal phosphate as a prosthetic group, as shown by the stimulation obtained on addition of this compound and by the inhibitory effect of some carbonyl reagents. There seems to be no requirement for, divalent metal ions since Mg^{++} does not stimulate and EDTA does not inhibit the reaction. The enzyme is inhibited by Hg^{++} ions and *p*-chloromercuribenzoate.

The evidence presented classifies the formation of β -cyanoalanine into the group of pyridoxal phosphate catalysed β -replacement reactions of serine and cysteine. Some of the enzymes carrying out such reactions are known to deaminate their amino-acid substrate, particularly serine, in the absence of the second reactant. However, no formation of pyruvate could be detected on incubating cyanoalanine synthetase preparations with either labelled serine or labelled cysteine in the absence of cyanide. Likewise, a preparation of cystathionine synthetase which also deaminates serine did not synthesize β -cyanoalanine.

A number of other organisms was assayed for cyanoalanine synthetase. β -Cyanoalanine formation was demonstrated in an extract of *Vicia sativa* seedlings, and in mitochondria from seedlings of sorghum, barley, safflower, flax and mung beans. In addition to these plant sources, cyanoalanine synthetase activity was found in an extract of *E. coli* (cf. ref. 7), but not in homogenates or mitochondria of rat liver.

The part played by cyanoalanine synthetase in the living cell is not fully understood. It may serve to dispose of HCN in those plants containing cyanogenic glucosides and the location of the enzyme in the mitochondrion is of particular interest. However, its occurrence is not restricted to such plants and the physiological significance of this enzyme in organisms not known to have cyanogenic compounds is obscure.

Thalidomide as a Possible Biological Acylating Agent

THE teratogenic activity of thalidomide is now well known, but the mechanism by which the drug produces foetal abnormalities is obscure. Recent investigations in this laboratory¹ on the relationship between embryotoxic activity and chemical structure in a series of compounds related to thalidomide (α -phthalimidoglutarimide) suggested that the phthalimide portion of the molecule is important in determining teratogenic activity. Replacement of the phthalimide ring of thalidomide by other ring systems such as those of succinimide and hexahydrophthalimide was found to lead to the loss of embryotoxic activity in the rabbit. However, replacement of the glutarimide ring of thalidomide by other groups did not in every case lead to complete loss of embryopathic activity, for 4-phthalimidobutyramide, phthalimidobenzene and 2-phthalimidoglutaric acid anhydride were still embryotoxic in rabbits but much less so than thalidomide. These observations suggested that an *N*-substituted

phthalimide structure was essential for embryotoxic activity. However, the exact structural requirements in the *N*-substituent for embryotoxicity are not yet clear, but, so far as is known at present, optimum embryotoxic activity is found when the *N*-substituent is α -glutarimide as in thalidomide itself.

These findings raised the question of the possible significance of the *N*-substituted phthalimide structure in biological systems, and this may be considered from two aspects. In the first place, it is possible that the phthalimide structure (1,3-dioxoisindoline) is closely related to some substance involved in the metabolism of the embryo, and thereby interferes in some essential reaction. But, so far as we are aware, the phthalimide structure does not occur naturally. The second possibility is that the embryotoxic activity of certain phthalimide derivatives is a function of their chemical reactivity. It is possible that certain *N*-substituted phthalimides, because of a particular chemical reactivity, are able to interact with certain chemical substances essential to the normal development of the embryo and thereby cause malformations or death. Such an interaction would be a biochemical basis upon which the embryotoxic effects of thalidomide and related *N*-substituted phthalimides could be explained.

In this communication, preliminary evidence is presented which indicates that, under certain conditions, thalidomide behaves as an acylating agent and is able to acylate certain aliphatic diamines of biological interest such as putrescine and spermidine.

Our interest in the acylating activity of thalidomide arose from the discovery, in this laboratory, that thalidomide, at physiological pH values, is hydrolysed and, in effect, the drug acylates water, forming mainly α -(*o*-carboxybenzamido) glutarimide². The ability of thalidomide to acylate the hydroxyl group of water suggested to us that it might also react with hydroxyl or amino groups in other compounds. In fact, it is well known that phthalimide itself will acylate hydrazine to form *o*-carbamylbenzoylhydrazide (ref. 3). The progress of an acylating reaction involving the phthalimide ring of thalidomide can be readily followed spectrophotometrically. The intact phthalimide ring system exhibits an intense ultra-violet absorption at 220 m μ (ref. 4). Cleavage of the five-membered ring of phthalimide results in a marked decrease in this absorption so that the extent of ring-splitting following an acylation reaction can be readily estimated by measuring the decrease in optical density at 220 m μ (ref. 5). Using this procedure we have been able to follow the ability of thalidomide to acylate a number of compounds containing hydroxyl or amino groups in the absence of water.

Thalidomide (4×10^{-5} M) in absolute ethanol containing the test compound (10^{-3} M) was incubated at 37° C for periods up to 10 h. Samples of the incubates were withdrawn at hourly intervals and the optical density at 220 m μ was measured in a Unicam 'SP 500' spectrophotometer. The optical densities so obtained were compared to those of a similar solution of thalidomide in ethanol. In ethanol solution, thalidomide is stable, and no change in optical density at 220 m μ is detectable. In cases where acylation occurred, the disappearance of the thalidomide and the appearance of acylation products were confirmed chromatographically using the solvent systems already described by us⁶.

Table 1 gives a list of ten compounds whose ability to interact with thalidomide was tested. Thalidomide does not, under the conditions of the experiment, react with glucose nor the simple monoamines, *n*-butylamine, *n*-octadecylamine and ethanolamine. However, the aliphatic diamines, putrescine and spermidine, interacted rapidly with thalidomide, while ethylenediamine, cadaverine and spermine reacted less readily. Thus, when thalidomide was incubated with spermidine at 37° C for 2 h, the drug completely disappeared from the incubation medium, as was shown spectrophotometrically and chromatographically.

Table 1. ACYLATING ACTIVITY OF THALIDOMIDE TOWARDS VARIOUS ALIPHATIC AMINES AND OTHER COMPOUNDS

Compound incubated with thalidomide	Percentage thalidomide disappearing in 2 h at 37° C
Glucose	0
<i>n</i> -Butylamine	0
<i>n</i> -Octadecylamine	0
Ethylenediamine	3
1,4-Diaminobutane (putrescine)	72
1,5-Diaminopentane (cadaverine)	27
1-(3'-Aminopropylamino)-4-aminobutane (spermidine)	100
1,4-Di(3'-aminopropylamino)butane (spermine)	28
Ethanolamine	0
γ -Aminobutyric acid	0

Thalidomide (4×10^{-5} M) and the compound under test (10^{-3} M) were incubated together in absolute ethanol at 37° C for periods up to 10 h. Spermine, however, was tested at a concentration of 10^{-2} M.

It is possible that the reactivity of thalidomide towards certain natural diamines may be of significance in relation to the biological properties of the drug. This aspect of the reactivity of thalidomide is being further investigated.

'Buried' Tyrosyl Residues and the Activity of Trypsin

CHEMICAL modifications of enzymes have generally been used to identify catalytically functional amino-acid residues. Thus, inactivation with diisopropylphosphorofluoridate (DFP) has identified a number of 'seryl' enzymes¹ and interaction with alkylhalides or *para*mercuribenzoate (PMB) has defined a group of sulphhydryl enzymes². Similarly, we have used *N*-acetylimidazole to demonstrate a 'tyrosyl' enzyme, carboxypeptidase A (ref. 3).

The categorization of enzymes in terms of catalytically functional, active-centre residues is the direct consequence of the chemical specificity of selective reagents. Such reagents can also serve to identify amino-acid residues which function primarily through maintaining the structure of enzymes rather than participating directly in their catalytic mechanisms. In many enzymes, thiol residues may become reactive only after denaturation³. These unreactive or 'buried' thiol groups are thought to be internally bonded, thereby stabilizing structure in a manner as yet undefined, but distinct from disulphide linkages.

Similarly, 'buried' tyrosyl residues (the terminology here employed has been discussed previously⁴) are thought to maintain structure, for example, through tyrosyl-carboxylate hydrogen bonds, as shown for ribonuclease^{4,5}.

We have now acetylated trypsin with acetylimidazole and the experiments reported here provide evidence that in this enzyme, also, 'buried' tyrosyl residues stabilize tertiary structure. This stabilization is required for the function of the enzyme, presumably by maintaining the critical conformation of the active centre.

Acetylimidazole has been shown to be a relatively specific agent for the *O*-acetylation of 'free' tyrosyl residues of proteins. Experimentally, the degree of acetylation is apparent by a marked decrease in molar absorptivity at 278 m μ ². In a series of proteins, the number of tyrosyl residues acetylated with acetylimidazole at pH 7.5 corresponded quite closely to the number of

'free' residues measured by *pH* titration⁶. Thus, this reagent permits the selective acetylation of those tyrosyl residues of native proteins which are readily accessible to the ambient medium. Reaction of all of the tyrosyl residues of a protein can be achieved subsequent to denaturation⁶.

Previously, we have reported that 6.7 of the 10 tyrosyl residues of trypsin can be acetylated with acetylhydrazole at *pH* 7.5 without loss of enzymatic activity⁸. This number of 'free' tyrosyl residues is in substantial agreement with the data of Inada *et al.*⁷, who have shown, by titration, that six groups are 'free' while four appear to be 'buried'. Since urea denaturation of trypsin is reversible⁸ and exposes the 'buried' tyrosyl residues (see Table 1, column 3), we have acetylated the enzyme in urea with acetylhydrazole and studied the resultant enzymatic changes (the minor discrepancy in the number of 'free' tyrosyls determined by titration and by acetylation might be due to a partially 'buried' residue as discussed elsewhere^{8,9}).

Table 1. EFFECT OF ACETYLATION ON THE ESTERASE AND PEPTIDASE ACTIVITIES OF TRYPSIN

	Peptidase <i>V/V_c</i>	Esterase <i>V/V_c</i>	O-Acetyltyrosyl mole/mole
1. Trypsin	1.0	1.0	0
2. Trypsin + 3.2 M guanidine	0.5	0.5	0
3. Trypsin + acetylhydrazole	1.1	0.9	6.7
4. Trypsin + 3.2 M guanidine + acetylhydrazole	0.1	0.0	10.2

Peptidase activity was determined by the hydrolysis of casein¹⁷ and esterase activity was determined by the hydrolysis of benzoylarginine ethyl ester¹⁸ using a *pH*-stat. Acetylation was carried out with a 120-fold molar excess of acetylhydrazole at 20° and *pH* 7.5 in 0.01 M *tris* buffer ± 3.2 M guanidine HCl.

Twice crystallized salt-free lyophilized trypsin (Worthington Biochemical Corporation) was dissolved in 0.01 M *tris* buffer at *pH* 7.5 and acetylated with a 120-fold molar excess of *N*-acetylhydrazole (K. and K. Laboratories) at room temperature⁸. After 30 min, an aliquot was removed, diluted and assayed for esterase and peptidase activities (Table 1). Compared with the native enzyme, there is no change either in peptidase or esterase activity. However, when the enzyme is acetylated in the presence of 3.2 M guanidine hydrochloride (Table 1) or 8 M urea (Fig. 1), both activities are virtually abolished, though the controls remain active. The abolition of enzymatic activity is accompanied by the acetylation of the buried tyrosyl residues as measured by spectral changes. In 0.01 M *tris* buffer 6.7, but in 8 M urea all 10, tyrosyl residues of trypsin are acetylated (Table 1, column 3). The esterase and peptidase activities of such acetyl-

Fig. 1. Changes in esterase (closed symbols) and peptidase (open symbols) activities on acetylation of trypsin: ●, ○, Trypsin in 0.01 M *tris*, *pH* 7.5, and trypsin in 0.01 M *tris*, *pH* 7.5 + 120 molar excess acetylhydrazole; ■, □, trypsin in 0.01 M *tris*, 8 M urea, *pH* 7.5, and (▲, △) trypsin in 0.01 M *tris*, 8 M urea, *pH* 7.5 + 120 molar excess acetylhydrazole.

Fig. 2. Inactivation of trypsin by acetylation in 8 M urea and reactivation by deacetylation with 1 M hydroxylamine. A 120-fold molar excess of acetylhydrazole was added to trypsin in urea and activities were measured as a function of time — — —. After 30 min the acetylation mixture was made 1 M in hydroxylamine (indicated by arrow), and esterase (closed symbols) and peptidase (open symbols) activity measurements continued (—). Activities are expressed relative to the control sample measured at the same time.

trypsin, inactive in 8 M urea, are restored to the control values by deacetylation with 1 molar hydroxylamine (Fig. 2). Since the active centre O-acetyl serine is not stable at *pH* 7.5 (ref. 10), the reactivation of the acetylated, inactive enzyme with hydroxylamine suggests that the acetylation and deacetylation of 'buried' tyrosyl residues accounts for the reversible abolition and restoration of activity. These results are consistent with the hypothesis that at least one buried tyrosine is essential to the maintenance of the active configuration of trypsin.

Reversibly denatured trypsin has been inactivated by acetylation in dimethylsulphoxide with acetic anhydride^{11,12}. Under these conditions, however, only lysyl residues were modified and the inactive acetyltrypsin could not be reactivated; hydroxylamine was not used.

A critical structural role of a specific 'buried' tyrosyl residue in trypsin has been proposed on the basis of activity changes which accompany ionization of the enzyme⁷. The alkaline limb of the *pH*-rate profile of trypsin coincided with the ionization curve of the four 'buried' tyrosyl residues, one of which was thought to be essential to the maintenance of the active centre. Ionization of the 'free' tyrosyl residues did not affect activity.

Amino-acid sequence is thought to be a major determinant of secondary and tertiary protein structure¹³. Acetylation of 'buried' tyrosyls in trypsin disrupts the normal sequence and may thereby prevent reformation of one or several specific internal tyrosyl linkages, broken by urea or guanidine. Alternatively, acetylation may preclude proper three-dimensional re-alignment of the molecule, solely through steric effects. The restoration of activity to trypsin by regeneration of internal tyrosyl bonds appears analogous to restoration of activity in ribonuclease by regeneration of disulphide bridges. It may well be that in the latter instance both processes, operating simultaneously, mutually facilitate proper re-alignment. (Similar conclusions regarding the role of 'buried' tyrosyl residues in ribonuclease have been reached by a different approach, that is, inhibition of oxidative reactivation of the reduced enzyme by analogues of tyrosine¹⁴). 'Buried' lysyl residues may also have structural importance in trypsin as suggested by the results of acetylation in dimethylsulphoxide^{11,12}, though acetylation of tyrosyl residues was not entirely ruled out in this instance.

The present observations extend the information concerning the essentiality of tyrosyl residues in the mechanism of enzyme action. Two of the seven 'free' tyrosyl residues of carboxypeptidase have been shown to be essential for the interaction of this enzyme with peptides¹⁴; however, on acetylation of these two tyrosyl residues, the esterase activity of this enzyme increases about seven-fold, while peptidase activity is virtually abolished^{3,15}. Acetylation of trypsin exposed to guanidine or urea abolishes both esterase and peptidase activities by rendering the 'buried' tyrosines accessible to acetylimidazole. Since these critical tyrosyl residues in trypsin are 'buried' they cannot be considered functional in the same sense as the 'free' tyrosines of carboxypeptidase, that is, by interacting directly with substrate. Rather, they appear to be responsible for maintaining the active centre of the enzyme in the configuration required for catalysis.

Comparison of Salivary Amylase-levels in the Human Male and Female

In 1940, Lacassagne¹ demonstrated sexual dimorphism in the submandibular glands of mice and other rodents. Later, Raynaud and Rebeyrotte^{2,3} found that the amylase-level of saliva from male mice is 50 per cent higher than that of female mice. They also reported that administration of testosterone propionate to female mice raised their salivary amylase-level to that of untreated males and that castration of males reduced their amylase-level to that of normal females. Swigart *et al.*⁴ have reported that the amylase content of the submandibular glands of male mice is three times that of the female, that castration reduced the submandibular gland amylase-level of the male mice to less than 50 per cent of normal and that administration of testosterone to castrated females raised the submandibular amylase-level to a level comparable to that in the male.

The observations reported here were carried out in an attempt to determine whether any sex-linked differences exist in the salivary amylase-levels of man.

Saliva samples for these experiments were collected from each of ten men and ten women aged between 20 and 46. Each subject contributed saliva on three separate occasions, 2-4 weeks apart. In all cases saliva was collected at the same time of day, between 10 and 11 a.m. All subjects had rinsed their mouths thoroughly before collecting saliva and salivary flow was stimulated by chewing gum from which sugar and flavouring was first removed by preliminary chewing.

The saliva samples were centrifuged to remove any solid particles and dilutions of 1:1000-1:5000 were prepared with 0.9 per cent sodium chloride. Amylase activities were determined by the method of Van Loon *et al.*⁵, carrying out each determination in duplicate or triplicate. Values for salivary amylase are given in Van Loon units per 100 ml. Van Loon units are numerically equivalent to Somogyi units.

The value given for each individual subject in Table 1 is the average of the determinations carried out on three different samples, collected as indicated earlier at several weekly intervals. Salivary amylase-levels in these three different samples from the same individual varied from one another by as little as 10 per cent in some cases and as much as 50 per cent in others. The mean of these averages for male subjects was 84,900 and, for the female subjects, 80,400. Using the student 't' test as outlined by Snedecor⁶, the t-value for the difference in these two groups is 0.35. Snedecor's table indicates that the t-value should be at least 2.87 at the 1 per cent level of confidence and at least 2.10 at the 5 per cent level for the difference seen in the salivary amylase-levels of these two groups to be considered statistically significant. The t-value of 0.35 indicates that the difference is not significant. The probability that such a difference will occur by chance is 98 per cent.

Table 1. HUMAN SALIVARY AMYLASE-LEVELS

	Salivary amylase in units/100 ml.	
	Male	Female
(1)	94,700	94,000
(2)	64,600	33,100
(3)	85,600	88,600
(4)	64,600	65,900
(5)	115,100	92,400
(6)	96,800	122,200
(7)	50,300	91,600
(8)	93,500	72,000
(9)	76,800	23,800
(10)	106,500	120,000
Mean	84,900 ± 3,160*	80,400 ± 9,770*

* Standard error of the mean.

The salivary amylase-levels for all three determinations for each female subject were examined in relation to the subject's menstrual cycle and the times of collection of saliva. No correlation could be established. For one female subject, determinations were then undertaken of her salivary amylase-level on samples taken daily throughout seven menstrual cycles. Variations in amylase-level occurred during the cycle studies, but again none of the changes could be correlated with hormonal changes during the cycle.

It is apparent, then, that while there is considerable variation in the salivary amylase-levels of different individuals from week to week, both male and female, there is no statistically significant difference in the salivary amylase-levels of the human male and female and no salivary amylase changes attributable to hormonal changes during the menstrual cycle are seen in the female.

Acid Mucopolysaccharide and Hexosamine Metabolism in Dermal Connective Tissue of Adrenalectomized Rats

SINCE steroids have been reported to be involved in the metabolism of the mucopolysaccharides of the dermis¹⁻³, it appeared interesting to investigate the effect of adrenalectomy on the amount of acid mucopolysaccharides and hexosamines in dermal connective tissue. The investigations were performed on young male rats of the CFE strain. Animals in the experimental group were adrenalectomized when 30 days old; they weighed 95-100 g at this time. Both adrenalectomized and control animals were purchased from Carworth Farms, Inc., New York City, Rockland County, New York. The animals were fed *ad lib.* 'Wayne Lab Blox' (mice and rats) diet. The adrenalectomized rats received 2 per cent sodium chloride in tap water, those of the control group were given tap water alone; both beverages were offered *ad lib.*

The animals were killed when 60 days old (average weight 240 g) by incising the aorta. Their skin was shaved, freed from adherent muscles by scraping with blades, ground into paste in a mill (Wiley laboratory mill, intermediate size) and weighed. One portion of the 'fresh skin' (15-20 g) was defatted with acetone in a Soxhlet extractor, dried at 80° C in a drying oven and used for mucopolysaccharide as well as total hexosamine determination. The other portion of 'fresh skin' (about 1 g) was successively extracted with 0.154 M, 0.5 M sodium chloride and finally with 0.5 M sodium citrate. The hexosamine content was determined (Ehrlich method according to Blix⁴) in these extracts, in soluble residue and in a portion of dry defatted skin after hydrolysis with 6 N hydrochloric acid at 104° C for 4 h.

The acid mucopolysaccharides were extracted, fractionated and determined as described earlier⁵. For this, the dry defatted samples (3-6 g) were digested with papain*, then with trypsin* using respectively 4 and 3 mg of these

* Papain (three times recrystallized) and trypsin (twice recrystallized, free of salt), supplied by Worthington Biochem. Corp., Freehold, New Jersey.

enzymes per gram of dry fat-free tissue. The liberated polypeptides and amino-acids were separated by dialysis. The mucopolysaccharides were precipitated with cetylpyridinium chloride (CPC) and the precipitate washed with 0.03 M sodium chloride. Then the mucopolysaccharide-CPC complex was successively extracted with 0.4, 1.2 and 2.1 M sodium chloride in order to solubilize and separate the three types of mucopolysaccharides, that is, 'hyaluronic acid', 'chondroitin sulphates' and 'heparin' as in the procedure of Schiller *et al.*⁷. The content of various mucopolysaccharides was determined by the carbazole method according to Bitter and Muir⁸ using glucuronic acid as the standard.

The results are given in Tables 1 and 2. The values for mucopolysaccharides are expressed as μ mg of glucuronic equivalent per gram of dry defatted skin. The values for hexosamine obtained for different fractions are given in mg per gram of dry defatted skin. Comparing the results obtained with normal and adrenalectomized animals no significant difference was found in hexosamine content as well as in that of the various mucopolysaccharides. The ratio of total hexosamine to hydroxyproline (Stegemann's method⁹) for dry defatted skin was 0.044 for adrenalectomized and 0.047 for intact rats.

It was previously reported that the hexosamine content accounted for by mucopolysaccharides which contain uronic acid represented only a small portion of the total hexosamine occurring in the dermal tissue¹⁰. Similar results were also reported by Boas¹¹ for subcutaneous tissue. The present study confirms these findings since the total hexosamine content in the skin of both normal and adrenalectomized rats was approximately thrice that of uronic acid (Tables 1 and 2).

These results do not contradict those previously reported on dermal mucopolysaccharides of normal intact animals treated with corticosteroids¹⁻³, since the concentration of these compounds in the dermis of such animals was never determined. (At present Schiller *et al.*¹² have found a decrease in the hyaluronic acid and chondroitin sulphate contents in the dermis of intact rats treated with hydrocortisone.) As recently shown by Schiller¹², the previously reported decreased uptake of sulphur-35 (refs. 1-3) and carbon-14 (ref. 3) by skin mucopolysaccharides of rats pretreated with cortisone and hydrocortisone is not necessarily related to a reduced tissue concentration of acid mucopolysaccharides. Moreover, Bostrom *et al.*⁴ found no significant effect of hydrocortisone on the inhibition of uptake of sulphur-35 by the heart valve mucopolysaccharides.

Boas¹¹ found in adrenalectomized rats, an increase (about 20 per cent) in the total hexosamine content of

Table 1. CONCENTRATION OF ACID MUCOPOLYSACCHARIDES IN THE SKIN OF NORMAL AND ADRENALECTOMIZED RATS

No. of animals	Total concentration μ mg uronic acid/g dry skin	Distribution of uronic acid (%)		
		Hyaluronic acid	Chondroitin sulphates	Heparin
		Normal rats		
6	1,060 \pm 358	54.8 \pm 6.5	30.1 \pm 1.8	6.1 \pm 2.0
		Adrenalectomized rats		
14	1,166 \pm 262	51.2 \pm 1.7	44.1 \pm 2.0	4.8 \pm 2.3

Table 2. CONCENTRATION OF HEXOSAMINE AND NITROGEN IN THE SKIN OF NORMAL AND ADRENALECTOMIZED RATS (MG/G DRY DEFATTED TISSUE)

	No. of animals	Fresh skin				Obtained on defatted dry skin*
		Extracting medium:			Insoluble fraction	
		0.154 M NaCl	0.5 M NaCl	0.5 M Na-citrate		
Hexosamine Nitrogen	9	Normal rats				
		1.14 ± 0.09 20.3 ± 1.3	0.44 ± 0.06 14.3 ± 1.0	0.19 ± 0.02 6.2 ± 0.9	1.65 ± 0.19 112.2 ± 6.4	3.35 ± 0.10 156 ± 3.2
Hexosamine Nitrogen	21	Adrenalectomized rats				
		1.01 ± 0.12 18.2 ± 0.40	0.43 ± 0.07 15.6 ± 0.60	0.18 ± 0.04 5.51 ± 1.2	1.49 ± 0.09 120.7 ± 13.9	3.22 ± 0.22 154 ± 3.3

* Values found by separate determinations on dry defatted skin. The proportion of dry defatted tissue, based on wet weight, was 29.6 \pm 0.8 per cent for normal and 31.9 \pm 0.4 per cent for adrenalectomized rats. The ratio of hexosamine to hydroxyproline was 0.047 and 0.044, respectively, for defatted dry skin of normal and adrenalectomized rats.

subcutaneous tissue. However, because of the different nature of the tissue (subcutaneous versus cutaneous) and the short period of time between adrenalectomy and the test (10 days) used by Boas, the result cannot be compared with present findings.

From the comparison of the present data with those obtained earlier on hypophysectomized rats¹⁴ it is apparent that neither adrenalectomy nor hypophysectomy altered the gross mucopolysaccharide concentration in the skin. Contrariwise, the hexosamine content of the dermis modified by hypophysectomy¹⁰ was not affected in the skin of rats with ablated adrenals.

Adrenalectomy and hypophysectomy were previously reported to affect markedly the activity of compounds altering connective tissue permeability¹⁵. Our earlier *in vivo* and *in vitro* investigations have suggested that hyaluronic acid is an important factor regulating connective tissue permeability^{16,17}. The fact that mucopolysaccharide concentration is not altered by adrenalectomy is in agreement with our previously suggested hypothesis that the effect of substances altering tissue permeability may be related mainly to a different degree of polymerization of hyaluronic acid and seems to be independent of the gross mucopolysaccharide concentration¹⁵.

In conclusion, the results recorded here show that adrenalectomy does not affect mucopolysaccharide or the hexosamine contents of skin of two-month-old rats tested a month after ablation of the adrenals.

Occurrence of Odd-numbered Fatty Acids in the Mullet *Mugil cephalus*

ODD-NUMBERED fatty acids (C_{15} , C_{17} , C_{19} and C_{21}) in marine oils are normally found to total 1-4 per cent of the acids of all chain-lengths. This is most reliably indicated by gas-liquid chromatography of hydrogenated ester samples, since minor amounts of unsaturated odd-numbered fatty acids may be overlooked or confused with acids of the predominant even-numbered chain-

lengths. An exception to these typical compositions is the oil of the striped mullet *Mugil cephalus*, which has been found to contain up to 25 per cent saturated, mono-unsaturated and poly-unsaturated odd-numbered fatty acids¹⁻³.

A survey of fatty-acid compositions as determined by gas-liquid chromatography for phytoplankton, zooplankton and other lower marine organisms, including a few molluscs feeding on phytoplankton, does not suggest that odd-numbered fatty acids would occur in the diet in proportions high enough to influence the depot-fat composition of the mullet. The lugworm *Arenicola marina* from European waters is, however, reported⁴ to have an unusually high proportion of odd-numbered fatty acids. Unless the metabolism of the mullet is unusual in some respect, a view which has been discounted⁵, an alternative to a diet high in longer-chain odd-numbered fatty acids must be sought.

It has recently been found in this laboratory⁶ that a culture of the coccolithophore *Syracosphaera carterae* (courtesy of Dr. J. McLachlin, Atlantic Regional Laboratory, National Research Council of Canada) contained equal proportions (about 4 per cent each on a wet weight basis) of extractable lipid and of a material tentatively identified on the basis of its behaviour with cold alkali^{5,6} as dimethyl- β -propiethetin (or dimethyl-2-carboxyethyl sulphonium chloride). This thetin is found in a number of marine algae⁷, although the species investigated have usually been sessile forms and not planktonic. Lesser proportions of the thetin were found in five other species (out of a total of fourteen investigated) of unicellular planktonic algae.

The death of the host alga has been shown in at least one instance to lead rapidly to enzymatic degradation of the thetin with dimethyl sulphide and acrylic acid as the principal products⁷. Propionic acid has also been suggested as a product⁸. In carnivorous fish such as the Pacific chum salmon⁹ or Atlantic cod⁵ the digestive processes apparently do not break down the thetin, but dimethyl sulphide may be found in the fish at certain times^{8,9}, indicating that natural decomposition does occur, probably in a zooplankton¹⁰.

Propionic acid is accepted as a precursor of odd-numbered fatty acids^{11,12}, as has been demonstrated by feeding mice¹³. It has been suggested that acrylic acid may be associated with propionic acid in some metabolic roles^{14,15}, although acrylyl-CoA acts as an inhibitor of normal fatty acid synthesis¹⁶ and acrylic acid inhibits β -oxidation¹⁷. There is no evidence that the basic pathways of fatty acid metabolism in fish differ significantly from those in mammals.

It is therefore suggested that the odd-numbered fatty acids in the mullet may originate in very high proportions of propionic acid or related materials derived from the thetin in the diet, particularly in relation to the total lipid ingested from the same primary phytoplankton food source. The mullet is stated to feed extensively on diatoms and foraminifera, sometimes at the surface, but primarily on mud bottoms, and mud is commonly found in the digestive tract. The omission of zooplankton from the food chain and a digestive system somewhat different from that of the carnivorous species of fish could lead to decomposition of the thetin during digestion by the mullet. The metabolism of intact thetin in fish livers, where it may act as a methyl donor, varies appreciably between chum and red salmon⁸, and may also be markedly different in the mullet.

Syracosphaera is a tropical to subtropical species (the culture was grown at 21°C) and the occurrence of the thetin in one or more species of algae in the gulf of Mexico is entirely probable. At certain times of the year such algae might form a major part of the diet of the mullet, leading to the synthesis of odd-numbered fatty acids in high proportions. Once formed, these acids would be unlikely to be very actively removed from depot fats. The

lugworm analysis may be high in odd-numbered acids for similar reasons.

PHYSIOLOGY

Further Purification and Characterization of a Placental Protein with Immunological Similarity to Human Growth Hormone

Josimovich and MacLaren¹ purified a substance from human placentas which cross-reacted immunologically with antiserum to human growth hormone in Ouchterlony's double-diffusion system. Moreover, they detected this substance in the blood and urine of pregnant women, thereby raising the possibility that it might be a new placental hormone. Investigation of the physiological role of this substance has been hampered by the limited supply of material. The relatively easy method outlined here yields substantially greater quantities of this substance than could be obtained by the previously described purification from fresh-frozen placentas².

Fraction VII, a by-product of the extraction of γ -globulin from human placentas, was obtained from Lederle Laboratories through the courtesy of Dr. P. Bell. When examined by starch-gel electrophoresis and by diffusion in Ouchterlony plates, it was found to contain considerable quantities of the desired substance. Two hundred g, dissolved in 0.05 M ammonium bicarbonate to make a 10 per cent solution (w/v) were stirred with 100 g (wet wt.) of diethylaminoethyl cellulose previously equilibrated for 24 h with 0.05 M ammonium bicarbonate. The ion-exchange medium was collected and washed repeatedly with 0.05 M ammonium bicarbonate until the absorbance of the washings at 278 m μ was less than 0.5. The active component was then eluted with 1.5 l. of 0.5 M ammonium bicarbonate. On freeze-drying, 5–8 g of powder were obtained.

Thirty g of this powder, dissolved in 300 c.c. of 0.1 M ammonium bicarbonate, were fractionated using a column of 'Sephadex G-100' (8 x 80 cm) previously equilibrated with the same buffer. A high concentration of the component which reacted with antiserum to human growth hormone was found in the peak of the retarded fraction (Fig. 1). This was pooled, lyophilized and 2–3 g of white powder were obtained as compared with 150 mg by our earlier method. On examination by starch-gel electrophoresis this fraction was still heterogeneous (Fig. 2), but it appeared similar to our previously purified preparation.

Five mg or more of the final fraction caused a small increase in the body-weight gain of hypophysectomized

Fig. 1. Absorbance at 278 m μ of effluents from a column of 'Sephadex G-100' 3 x 55 cm. One g of the fraction obtained by elution of DEAE with 0.5 M ammonium bicarbonate was applied. 12 ml./tube

rats. In some assays 1 mg or more caused a definite but limited increase in the width of the tibial epiphyseal cartilage (Tables 1 and 2). Dr. E. Knobil found no increase in the serum free fatty acids in three hypophysectomized monkeys 4 h after administering 10 mg/kg of the placental protein; human growth hormone is effective at one-twentieth this dose.

In 1953, Astwood³ reported a delay of oestrus in rats if prolactin were given within 24 h of the appearance of cornified cells in vaginal smears. The extension of the cycle equalled the number of days the hormone was injected. Table 3 shows the prolongation of the oestrus cycle of rats by subcutaneous injection of prolactin or of

2.8	3	2.7 \pm 0.1	1.7

* Ovine prolactin, 10 I.U./mg.

the placental protein. When 200 μ g of ovine prolactin were administered in divided doses for four days, the return of oestrus was delayed by more than 3 days in 6 of 10 rats. It is apparent that, following the injection of placental protein, the results are variable. One mg or less infrequently delayed the return of oestrus, but larger amounts caused prolongation of the cycles in a

greater percentage of rats, and 5 mg or more frequently caused pseudopregnancy.

Dr. R. W. Bates kindly assayed this preparation for prolactin activity using the pigeon crop sac response. By the systemic assay in adult pigeons (Table 4) the placental protein had a potency of 1.4 u/mg compared with 0.25-0.5 u/mg by the local intradermal method in juvenile pigeons⁴. However, there was a quantitative difference between prolactin and the placental protein in the slope of the dose-response curve and also in the mean maximum weight of the crop sac. The latter was only about 10 g for the placental extract, while it is about 20 g with prolactin. Therefore, it is difficult to assign an accurate ratio of potency to the placental protein.

Twelve days after virgin albino rabbits were given 150 u chorionic gonadotrophin intravenously, ovine prolactin or the placental protein was injected into the mammary ducts according to the method of Bradley and Clarke⁵. Five days later the animals were killed and the mammary glands were examined after stripping off the overlying skin. Although no attempt was made to establish the minimum effective dose, 500 μ g of the placental protein caused extensive milk formation in the sector of the mammary gland which was injected (Fig. 3).

Additional biological investigations are now in progress to define the physiological role, if any, of this interesting protein.

I thank Dr. E. B. Astwood for his advice.

Influence of the Cerebral Cortex on the Cuneate Nucleus of the Monkey

NEARLY all neurones in the dorsal column nuclei of the cat are either excited or inhibited by stimulation of the pericruciate cortex¹⁻³, the excitation being carried entirely by the pyramidal tract, while inhibition involves an additional route^{2,3}. The cortically excited neurones occupy deep and rostral sites in the dorsal column nuclei, near the pyramidal terminations^{4,5}, while the cortically inhibited neurones are found more superficially. The latter, usually hair-sensitive neurones, possess peripheral inhibitory surrounds⁶; they may be identified with the cluster neurones, receiving large synaptic terminals⁷. The former are more often touch-sensitive or pressure-sensitive neurones possessing peripheral facilitatory surrounds⁶. Thus, neurones excited from one region of cortex are similarly excited from other cortical regions, ipsilateral and contralateral; the same rule holds for inhibition^{1,2}. Few neurones have been observed with both types of cortical influence or with no cortical influence whatever.

By sharp contrast, less than half the neurones in the cuneate nucleus of the monkey seem to be under cortical influence—and those that are often suffer a mixed influence, depending on the site of cortical stimulation. Furthermore, quite unlike that in the cat, cortical excitation in the monkey can often be shown to be monosynaptic.

In this investigation, the dorsal column nuclei and pericruciate cortex were exposed in dial-urethane-anaes-

Fig. 3. Photograph of the mammary glands of a pseudopregnant rabbit. The glands in which milk is present (upper left and lower right) were injected with 500 μ g of the placental protein; the control gland was injected with saline.

thetized, curare-paralysed rhesus monkeys. Bipolar stimulating electrodes were placed on both precentral and postcentral arm and leg cortices, and needle electrodes were inserted into the palm and five digital phalanges of the hand ipsilateral to the cuneate recording site. Also, a concentric-needle electrode was stereotactically placed in nucleus ventralis posterolateralis for antidromic activation of certain cuneo-thalamic projection neurones. Micropipettes filled with sodium chloride were driven in a three-dimensional co-ordinate system with the obex as origin. Responses to 'natural' stimulation were also obtained.

Three-fourths of the cuneate neurones were isolated less than $1,000\mu$ in depth, in the lower component of a bimodal distribution. Of about 400 neurones, 44 per cent were measurably influenced by stimulation of one or more of the four cortical sites, and 90 per cent of these were isolated less than one millimetre in depth. Excitation and inhibition were observed equally often—but one in every ten of these neurones displayed both types of influence. Among the latter, nearly every possible combination of excitation and inhibition from the four cortical stimulus sites was observed. In fact, the pattern of cortical influence violated every rule established in the cat. Hair, touch, pressure and joint neurones were scattered throughout the nucleus and revealed all degrees of cortical influence. Cortically driven neurones, half of which could not be fired by any form of peripheral stimulation, were confined to a region⁸ about 1 mm in radius, centred 1.5 mm caudal and 1.5 mm lateral to the obex. Cortically inhibited neurones, on the other hand, were scattered throughout the nucleus. Only 38 per cent of the touch neurones were under cortical influence, while 74 per cent of the hair neurones could be affected. However, there appeared a pronounced tendency for touch neurones to be inhibited, while hair neurones received more than their share of excitation. Also, three in every five cortically affected neurones displayed large receptive fields, while nine in every ten neurones not affected by cortical stimulation possessed very small receptive fields.

The idea⁹ that cortically driven neurones are interneurones mediating inhibition on to the cuneo-thalamic projection neurones does not appear tenable in either the cat⁶ or the monkey. Although one in every four cortically driven neurones was shown to be a projection neurone, the highly restricted thalamic stimulus may have given a limited picture. Several of these projection neurones were monosynaptically driven from the cortex. Fig. 1 shows an intracellular recording of a small field, touch neurone fired antidromically from the thalamus at 0.7 msec latency and orthodromically from postcentral arm cortex in 3.0 msec and postcentral leg cortex in 1.0 msec; it was not affected by precentral stimulation. Evidently mild inhibition descended from the arm cortex, for 100/sec repetitive stimulation decreased the burst length; the decrease could not have resulted from recurrent inhibition, for similar stimulation of leg cortex increased the discharge reliably to two spikes. Alternatively, the route from

Fig. 1. Intracellular recording of neurone (1.0 lat, 2.0 caud, 2.6 deep) responding to tactual stimulation on ulnar half of dorsum of hand, from knuckles to wrist. A, Upper, response to thalamic stimulation (0.7 msec latency); middle, 100/sec stimulation; lower, 250/sec stimulation. B, Upper, response to 0.5 msec, 7.2-V square pulse to postcentral arm cortex; lower, 100/sec stimulation. C, Upper, response to 0.5 msec, 7.2-V square pulse to postcentral leg cortex; lower, 100/sec stimulation. Time pips are 1 and 5 msec

Fig. 2. Extracellular recording of neurone (1.0 lat, 1.0 caud, 1.2 deep) responding to hair deflexion anywhere over entire arm, shoulder, neck, side of head and half-way down torso. A, Response to 0.1 msec, 7.2-V pulse to skin of distal phalanges, from thumb (1) to little digit (5). Neurone responded well to 100/sec stimulation of any digit. B, Response to thalamic stimulation (0.5 msec, 7.2-V). C, Response to 100/sec thalamic stimulation. D, Response to 0.5 msec, 7.2-V pulse to postcentral arm cortex. Neurone followed 50/sec stimulation of cortex. Time pips are 1 and 5 msec

arm cortex to cuneate may not have been monosynaptic, and a cuneate interneurone may have been failing at 100/sec. Fig. 2 shows a wide field, hair neurone responding to electrical stimulation of all five digits, to the thalamus at 3.3 msec and to the postcentral arm cortex at 10.4 msec; all other cortical sites mildly inhibited the neurone. The late spikes produced by thalamic stimulation, a common occurrence, resulted either from excitation of a cortical loop to the cuneate nucleus or spread to some nearby, descending excitatory pathway. The former explanation is more likely, for such late spikes were the rule for cortically driven neurones, whether or not the neurones could be fired antidromically. The presence of these late spikes militates against hypothesizing a recurrent inhibitory loop, keeping brief the response of this neurone to skin stimulation.

The foregoing observations show clearly the hazards of extrapolating across such highly divergent phylogenetic lines as from carnivores to primates. Many of the properties and response patterns of the cat cuneate nucleus are seen in the monkey, but a wide variety of other patterns is also evident. From some point common to both, perhaps in late Cretaceous times, these two somatosensory relay systems have developed separate and distinctive organizations and may perhaps be treating their inputs in slightly different ways.

Differences in Variability of Discharge Frequency between Primary and Secondary Muscle Spindle Afferent Endings of the Cat

THE frequency of action potentials in a nerve fibre has long been known to be a function of the input intensity. Fluctuations in frequency when the stimulus is held constant have often been considered merely as unwanted 'noise' limiting the accuracy of the experimental results. However, these fluctuations may also limit the amount of information which can be transmitted down a nerve fibre and so are of interest *per se*. In a receptor or an isolated axon, these fluctuations may result from the basic processes of action potential initiation and are of interest in this context. If the variability had the same basis in different cells (for example, resistive noise), one would expect that it would be smaller, the larger the cell or axon, and this is often the case¹. However, one of us (P. B. C. M.) noticed that the discharge initiated from single secondary endings of muscle spindles of the cat seemed to be considerably more regular than that from the primary endings, though these latter have the larger afferent nerve fibres²; later this was also found to have been noticed by others^{3,4}.

In order to check this observation and to compare the predictions of two different mathematical models for the cause of the variability^{5,6}, approximately 200,000 inter-spike intervals from thirteen muscle spindle afferents (seven primaries, six secondaries) from the soleus muscle of the anaesthetized cat were analysed. Fusimotor activity was eliminated by section of the appropriate ventral roots. The methods of dissection⁷, classification of the afferent fibres^{2,7}, and application of stretches⁸ have been described previously. The discharge of single afferent fibres was recorded on magnetic tape for periods of 1-3 min, after stretching the muscle to a new length. Later, a high-speed timer and recorder⁹ measured the intervals between successive discharges to the nearest tenth of a msec and punched this in binary coded form on to eight-hole paper tape. These tapes were afterwards analysed by the English Electric KDF9 computer of the Oxford University Computing Laboratory.

Fifty or 100 intervals were sampled at a time from the longer periods of recording. The distribution of intervals of the second sample was compared to the first using Smirnov's lambda test. If the second sample was not statistically different at the 5 per cent level, it was added to the first sample to form an enlarged comparison sample and the process continued until a statistically different sample was found. Then the distribution of intervals and various statistics for the total comparison sample were printed out by the computer. The new sample, which was statistically different, was used to begin a new comparison sample. Statistically different samples were found more often than expected for a completely stationary process, and this could only in part be explained by the fact that noticeable adaptation often continued for a couple of minutes following a stretch.

Fig. 1 shows four examples of the relation between the variability of the discharge and its mean interval. For each of the endings, the coefficient of variation (the ratio of the standard deviation to the mean interval) is plotted against the mean interval on a log-log scale. Each point represents values for a sample of between 100 and 1,200 successive intervals; within a sample the intervals were normally distributed about the mean at the higher action potential frequencies. For the lowest frequencies the interval distributions were often positively skewed about the mean (more very long than very short intervals) as predicted by various mathematical models^{5,6}. The range of mean intervals was obtained by stretching the muscle to different lengths, all within the normal physiological range. Where, because of adaptation, the mean intervals of the discharges elicited by different length stretches overlapped, the coefficients of variation were similar. It will be observed for three of the endings (10-2, 10-5, 3-3)

that the coefficient of variation tended to fall to a constant value as the mean interval decreased. This was a typical finding and occurred for twelve of the thirteen endings. One primary ending (10-1, Fig. 1), however, behaved in almost the opposite manner and the reason for this is unknown. Such behaviour is not covered by the theories to be discussed and will not be further considered here.

The variability of all the primary and secondary endings was compared at a mean interval of 40 msec, which fell within the range of discharge of all the units examined. The average coefficient of variation for the seven primaries was 0.048 and the range was 0.035-0.068 (that is, the standard deviation was 3.5-6.8 per cent of the mean, and at the mean interval of 40 msec the average standard deviation was \pm msec). When the atypical primary ending was excluded the average was 0.045, and the range was 0.035-0.056. The average coefficient of variation for the six secondaries was 0.020, and the range was 0.018-0.023 (that is, the average standard deviation was 0.8 msec). In no case was the coefficient of variation for a secondary ending higher than it was for a primary ending at this particular interval (40 msec). The same was true for comparisons at shorter intervals. The greater variability of the primary endings was not due to their greater dynamic sensitivity² causing them to respond to small random movements of the electro-magnetic stretcher, for their variability did not change when the stretcher current was turned off and its position maintained by mechanical clamping (the filled circles of Fig. 1). Nor were the primary endings examined being significantly influenced by vascular pulsation, for this gives a rhythmic disturbance of their discharge, which is readily recognizable on the reciprocal pulse interval display⁸ which was observed throughout the recording; rather, the variation in their discharge appeared to be random. Thus it may be concluded that at frequencies above about 20/sec the secondary endings fire appreciably more regularly than do the primary endings. It therefore appears that they provide the more accurate signal of the length of the muscle, at least in the absence of fusimotor activity; for a given length of the muscle the absolute frequency of discharge of the two kinds of ending may be very similar². In addition, it may be noted that the length response of the secondary endings is much less disturbed by small dynamic stimuli than is that of the primary endings².

It is also interesting to consider the results in terms of the mathematical models of Verveen and co-workers^{1,5,10} and of Stein⁶ for the variability of neuronal discharge. Both models predict that the coefficient of variation should tend to a constant value at short intervals of discharge. This was indeed the observed behaviour. At very long

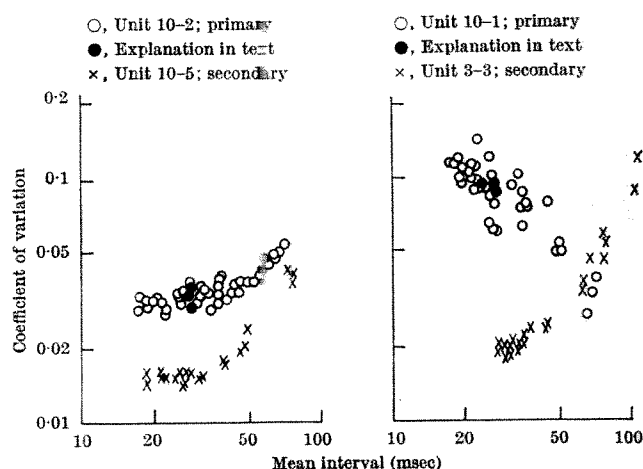

Fig. 1. The fractional variability of the discharge of single muscle spindle afferents plotted as a function of the mean inter-spike interval on a log-log scale.

intervals both models predict that the coefficient of variation should tend towards unity, the value for a random exponential distribution, but sufficiently long intervals for this situation have not been studied here. The region in which the coefficient of variation increases with increasing mean interval may be called the 'transition region', and here the two models lead to different predictions.

Verveen assumed that the disturbing noise which caused the variability was Gaussian in its distribution. This led him to conclude that in the transition region the standard deviation should increase as the square of the mean interval. The coefficient of variation should thus increase linearly with the mean interval, so that the right-hand side of plots such as those of Fig. 1 should tend to a straight line with a slope of 1. For the primary endings, the mean value of the slope in the transition region was indeed 0.98; but that of the secondary endings was 1.56, which seems to be too great a deviation to be readily accommodated by the theory. Stein's model⁶ assumes that there is a quantum or unit of excitation, and that these unit excitations occur randomly with a frequency determined by the stimulus and then decay exponentially in size with time. Summation and decay of unit excitations continue until threshold is reached. By computer simulation experiments (as in ref. 6) it has been found that in the transition region the coefficient of variation increases roughly as a power function of the mean, and that the power exponent increases as the number of quanta required to reach threshold increases. In addition, as the number of quanta increases, so the asymptotic value of the coefficient of variation decreases⁶. On both these criteria (high exponent, low asymptotic value) the excitation of the secondary ending would appear to depend on more quanta than that of the primary ending. The asymptotic values suggest that about 700 quanta are required to excite the primary ending to discharge, and that about 3,600 are required for the secondary endings. These figures also agree with computations based on the rather less accurate values of the slopes.

The nature of the quantal unit is, however, quite uncertain. One possibility is that it corresponds to the opening of a single pore in the receptor membrane, thus permitting the ionic flux which generates the receptor potential. A difficulty with this interpretation is that to give the best fit to our results the time constant for decay in the effectiveness of each quantum has to be 30–50 msec, which is far too long to correspond to the time-constant of the receptor membrane. Preliminary calculations indicate that this difficulty can be overcome if it is assumed that the closing of pores is also a random process and that the effectiveness of the pores is constant while open. This model yields very similar predictions and would fit the experimental results well if the mean time a pore stays open is of the order of 50 msec. It is possible that some of the variability may be due to other as yet unconsidered causes, such as the interaction of abortive impulses occurring in the different terminals of a single afferent ending¹¹.

Squid Giant Axon: Repetitive Responses to Alternating Current Stimulation

SINUSOIDAL alternating currents were used by Hill, Katz, and Solandt¹ to stimulate the frog sciatic nerve. At low frequencies of stimulation, repetitive responses caused discrepancies between the observed threshold values of current and the values predicted by Hill's theory of excitation². Teorell³ used triangular-wave alternating currents to excite action potentials in the *Nitella* cell. At low stimulus frequencies, two spikes per current cycle were occasionally observed. Repetitive all-or-none responses to constant currents were reported by Katz⁴ in frog sciatic nerve, by Hodgkin⁵ in single crustacean axons, and by Hagiwara and Oomura⁶ in the squid giant axon. Hagiwara and Oomura⁶ also stimulated the squid giant axon with linearly rising currents. In these experiments, single-action potentials were followed by a steadily increasing depolarization of the membrane, but repetitive action potentials did not occur. Tasaki⁷ obtained similar results when he used linearly rising currents to excite single toad-nerve fibres. The present research was undertaken to determine whether the squid giant axon could produce repetitive all-or-none responses to triangular-wave and sinusoidal alternating-current stimuli and to observe the responses at various current amplitudes and frequencies.

Giant axons 300–500 μ in diameter were isolated from the squid *Loligo pealii*. Stimulating and recording electrodes made of 50 μ silver wire were inserted longitudinally in an axon as it lay in a shallow pool of sea-water at a temperature of approximately 21° C. The stimulating electrode extended 7 mm in each direction from the recording electrode, which was 1 mm in length. Sinusoidal and triangular-wave alternating currents were supplied by a Hewlett Packard 202A function generator in series with a resistance of 0.5, 1, or 2 M Ω . A Tektronix 502 differential-input oscilloscope was used to measure the potential difference between the recording electrode in the axon and a return electrode in the sea-water pool. It is assumed that the observed potential differences largely appeared across the membrane.

Membrane potential was recorded as a function of current at stimulation frequencies in the range 20–1,000 c/s and with peak currents up to 37 μ amp. Typical data are presented in Fig. 1. Before and after alternating-current stimulation, each axon was tested for all-or-none excitability with short current pulses. Thirty-eight axons yielded acceptable data.

When the squid axon was stimulated by sub-threshold currents, the recorded voltage increased continuously with the current amplitude. The current and voltage waveforms were related in approximately the same way as the current through a series RC circuit is related to the voltage across the capacitor. Thus a sinusoidal current yielded a sinusoidal voltage, while a triangular current produced a voltage waveform consisting of consecutive curved segments. This behaviour is to be expected, since the resting membrane can be represented by an RC ladder network.

All-or-none action potentials appeared when the membrane was excited by the outward-flowing or positive phase of the alternating current. Threshold values of the stimulating current and of its amplitude were frequency-dependent. However, the threshold membrane potential was constant to within ± 10 mV when the axon was excited by sinusoidal and triangular current waves of all amplitudes and frequencies that were tested.

A train of repetitive action potentials was observed during each current cycle when the axon was stimulated at frequencies of 20–80 c/s. All-or-none responses rarely occurred at frequencies less than 20 c/s. The spike trains always began before the stimulating current reached its peak value and often continued after the current had

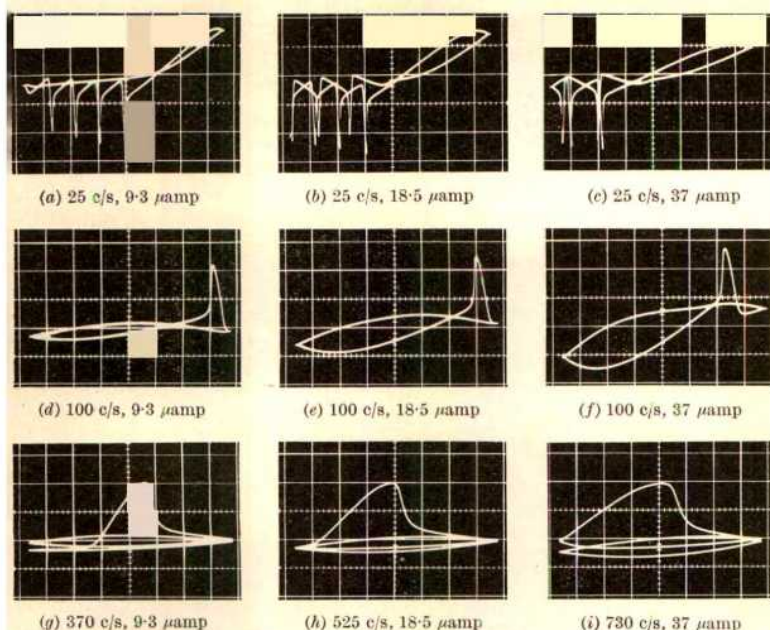

Fig. 1. Membrane potential as a function of triangular-wave current. Frequency and peak current of stimulus are indicated. Vertical scale: 50 mV/cm. Horizontal scales: (a), (d), and (g), 2.5 μ amp/cm; (b), (e), and (h), 5 μ amp/cm; (c), (f), and (i), 10 μ amp/cm. Positive current flows out of the axon.

begun to decrease. The threshold potentials of the individual spikes were approximately equal.

The trains of repetitive action potentials decreased in length as the stimulation frequency was increased. Typical lengths were four to six spikes at 25 c/s, two spikes at 50 c/s, and just one spike at 100 c/s. With frequencies in excess of 100 c/s, a single response occurred when the stimulating current had passed its peak and was decreasing. Above 150–300 c/s, a spike followed every second, third or fourth current maximum.

The preceding results may be compared with the data obtained by Hagiwara and Oomura⁶ when they stimulated the squid giant axon with linearly rising currents. In both studies, responses appeared at a critical membrane potential that was independent of the current and its time derivative. The alternating current, unlike the linearly rising current, was capable of eliciting repetitive responses, each of which occurred at approximately the same critical membrane potential.

This research was performed at the Marine Biological Laboratory, Woods Hole, Mass., while I was an employee of the National Institute of Mental Health, Bethesda, Maryland.

PHARMACOLOGY

Teratogenic Effects of Synthetic Compounds related to Trypan Blue: the Effect of 1,7-Diamino-8-naphthol-3,6-disulphonic Acid on Pregnancy in the Rat

In 1948 Gillman *et al.*¹ observed that the injection of the disazo dye, trypan blue, into pregnant rats produced congenital abnormalities in their offspring. Since then a number of papers dealing with the teratogenic

activity of several closely related dyes and chemical compounds, in various species, have been published, and attempts have been made to correlate molecular structure with teratogenic activity. Beaudoin and Pickering² tested several synthetic disazo compounds, and it is suggested, on the basis of their results, that a naphthalene nucleus with an NH_2 group in position 1, and two HSO_3 groups, preferably in positions 3 and 6, is at least necessary for teratogenicity. This communication reports the results of an investigation of the effect of such a compound—namely, 1,7-diamino-8-naphthol-3,6-disulphonic acid—on pregnancy in the rat.

Twenty female rats of a Wistar strain (average weight 200 g) were used. Preliminary experiments in non-pregnant does had shown that the LD_{50} (Kärber³) of the compound to be tested (hereafter referred to as compound A) was 66 mg/kg rat, so 5 mg in a distilled water solution were injected subcutaneously on day 8.5 of pregnancy. Control animals were injected with saline. The does were killed at 24-h intervals from 10.5 to 12.5 days of gestation, as pregnancies persisting beyond that time tended to be totally aborted. The uterine horns, liver, kidney, lung and spleen were removed and fixed in Bouin's fixative. After 24 h the

embryos were dissected out of their membranes in 70 per cent alcohol under a dissecting microscope, examined for abnormalities, and classified into developmental stages according to Christie⁴. The other tissues, including the placenta and yolk sac, were embedded in paraffin wax, and sectioned at 10 μ . Unstained sections, and sections stained with haematoxylin and eosin, were examined for the presence of dye granules, and for histological alterations, and compared with sections from the control pregnant animals.

Ascending chromatography of the compound tested, and of trypan blue, was carried out in *n*-butanol-pyridine-water (1:5:4 by volume) as described by Beck and Lloyd⁵.

Table 1. EFFECTS ON PREGNANCY OF AZO DYES OR RELATED COMPOUNDS INJECTED ON OR ABOUT DAY 8.5 OF PREGNANCY

Compound	No. of mothers	Pregnancies terminating before killing day	% Total resorption	% of all pregnancies	No. of implantations	% Survivors re-sorbed	% Survivors mal-formed
Control	11	0	0	100	113	6.2	0
Trypan blue	45*	4	16	80	407	44	49
Niagara blue 4B	15*	7	13	80	126	15	4
Compound 8	8†	0	0	100	76	14	3
α -Toluidine	10*	0	0	100	109	8	0
Compound A	20	35	35	30	61	13	0

* Data from Wilson (ref. 5).

† Data from Beaudoin and Pickering.

As can be seen from Table 1, the quantity of compound A injected (5 mg) produced an incidence of 35 per cent each for maternal death and total resorption before the killing day, these figures being higher than those quoted for any of the other compounds listed. In the surviving pregnancies, however, the average number of embryos per litter was no different from that in other experimental groups or controls. Some increase in the percentage resorption (13 per cent) was present, but was no greater than with the least toxic of the dyes tested.

Enlargement of the adrenals and spleen (as has previously been reported by Gillman *et al.*¹ for trypan blue) and of the kidney was present in the injected rats. Histological examination showed lymphoid hyperplasia in the liver, spleen and lungs. Degeneration of the cells of

the entire proximal convoluted tubule of the kidneys was found with accumulation of eosinophilic material within the remaining basement membrane and in the tubules in the outer medulla, in which cellular debris including droplets of basophilic material was present. The glomeruli, distal convoluted tubules and remaining kidney structure appeared normal. The placenta appeared normal in structure. No dye was found in the unstained sections of any of the tissues examined.

Table 2 shows the stage of development attained by the embryos at the time of killing. All exhibited general developmental retardation of the order of one half to one stage⁴, but no abnormalities were present. As the entire litter was either aborted or retarded in development, it seems probable that this was related to the degeneration of the renal proximal tubule in the mother, rather than to a direct effect of the dye on the embryos.

Chromatography of compound A showed that it was not identical with either of the commonly described red or purple contaminants of trypan blue.

Table 2. DEVELOPMENTAL STAGE OF EMBRYOS AT TIME OF KILLING IN INJECTED GROUP AS COMPARED WITH CONTROL RATS

Day of killing	Developmental stage	Normal stage reached
10-5 (1)	8 at stage 16	18-19
	7 at stage 17	
10-5 (2)	4 at stage 16	18-19
	4 at stage 17	
11-5 (1)	3 at stage 20 (early)	20 (late)-21
11-5 (2)	2 at stage 19	20 (late)-21
	9 at stage 20 (early)	
11-5 (3)	3 at stage 19	20 (late)-21
	5 at stage 20 (early)	
12-5	8 at stage 22 (early)	22 (late)

The chemical formulae of trypan blue and the other known teratogenic disazo dyes tested in Table 1 include two 8-naphthol rings (one in the case of compound 8) substituted in the 1 and 7 positions with amino groups, and with two sulphonic acid groups in the 3,6 positions, linked through di-*o*-toluidine, or di-*o*-anisidine. As *o*-toluidine has been found not to have teratogenic activity, it seemed likely that reduction of trypan blue *in vivo* over the disazo linkage could release the active part of the molecule, that is, compound A. However, this investigation has clearly shown that this is not so, and it would appear that it is to the whole molecule rather than parts of it that one must look for teratogenic activity.

I thank the Clayton Aniline Company for supplying the compound tested in this investigation.

Biphasic Dose-response Relationship with Acetylcholine on the Heart of the Mollusc *Tapes turgida*

THE heart of the mollusc *Tapes turgida* has been shown to be very sensitive to acetylcholine¹ and provides a satisfactory alternative to the heart of *Venus mercenaria*, a species not found in Australia, for the assay of acetylcholine.

In the experiments described here, only the ventricle was used, and this was suspended between threads tied at the anterior and posterior vessels, in an organ bath containing sea-water. In most experiments, oxygen containing 5 per cent carbon dioxide (carbogen) was bubbled through the bath, though in some, no aeration at all was provided. Under the conditions of assay,

when the bath fluid was changed frequently, the heart continued to beat constantly without aeration.

Acetylcholine produces a negative inotropic effect on the hearts of both *Venus* and *Tapes* and the dose-response relationship is particularly steep in both species. A concentration of acetylcholine between 10^{-10} and 10^{-9} g/ml. is generally sufficient to produce complete block.

During an examination of the effect of concentrations of acetylcholine less than 10^{-10} g/ml. we have found that the heart showed another inhibitory phase, often proceeding to a complete block, but only when aeration with carbogen was used. The dose-response curve over the range of acetylcholine concentrations studied showed a biphasic effect (Fig. 1).

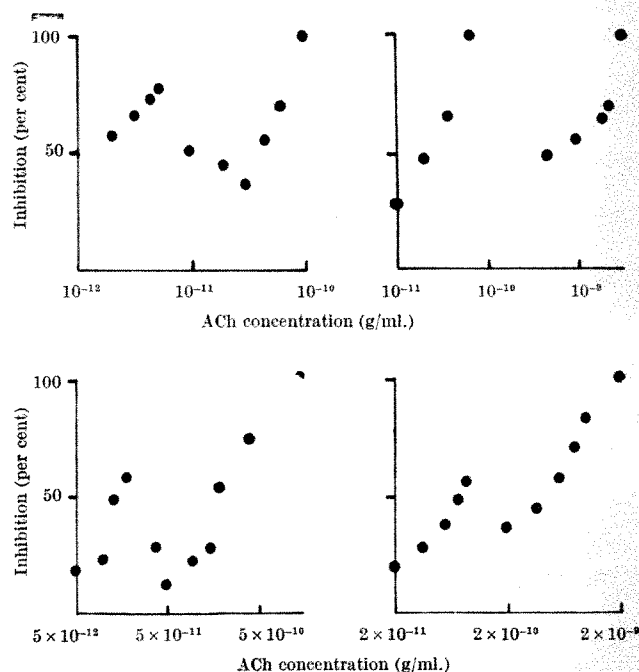

Fig. 1. Graphs showing the relationship between concentration of acetylcholine and the percentage reduction in the amplitude of the heart beat in four hearts of the mollusc, *Tapes turgida*

Preliminary experiments without aeration failed to reproduce inhibition at the lower concentrations of acetylcholine.

A similar biphasic dose-response relationship with acetylcholine has been described recently for the inhibitory effect on the perfused frog heart², and for the stimulation of the frog rectus abdominus muscle³.

This biphasic relationship presents an inherent source of error when the *Tapes* heart, aerated with carbogen, is used as an assay preparation for acetylcholine. Particularly is this so if the 'matching' technique is used, where the concentration of the unknown solution is estimated by matching a response on the heart (generally about 50 per cent inhibition) with that produced by a standard solution of acetylcholine.

With this technique it is possible to match responses produced by the unknown and standard solutions on different slopes of the biphasic dose-response curve.

However, preliminary experiments suggest that this difficulty does not arise if the heart is allowed to beat in sea-water without aeration.

HAEMATOLOGY

Synthesis of the α_1 -Glycoprotein (Darcy) of Rat Serum by the Liver

AN α_1 -glycoprotein present in normal rat serum has been observed to increase markedly in concentration in conditions characterized by tissue injury or cell death¹. Based on the reduced response of the protein to tissue injury in partially hepatectomized rats, it has been suggested that the liver is the tissue of origin^{2,3}. The present communication reports the demonstration of the synthesis of α_1 -glycoprotein (Darcy) by the liver during the acute phase of an inflammatory response.

An anaesthetized, adult, male rat of Sprague-Dawley origin weighing approximately 400 g was injected with 1.0 ml. of a sterile solution of spirits of turpentine, N.F., in corn oil (v/v); 0.5 ml. subcutaneously in the scapular area and 0.25 ml. intramuscularly in each thigh. Twenty-four hours later, the rat was exsanguinated by cardiac puncture under ether anaesthesia and the liver removed aseptically.

The tissue culture and radio-immuno-electrophoretic techniques described by Hochwald *et al.*⁴ and by Williams *et al.*⁵ were followed. The liver was minced and duplicate 500 mg (wet weight) portions were incubated in 25-ml. Erlenmeyer flasks containing 3 ml. of Hanks's buffered salts solution at 37°C for 30 min to deplete the system of amino-acids. The salts solution was removed and replaced by 3 ml. of a medium consisting of the vitamin mixture recommended by Eagle *et al.*⁶, 600 units penicillin, 600 μ g streptomycin, 0.5 per cent ovalbumin, and the following compounds (mmole $\times 10^{-3}$): glucose, 48; L-asparagine, 0.9; L-glutamine, 4.5; DL-tryptophan, 0.09; and L-hydroxyproline, 0.45. As a source of other essential amino-acids and the radioactive label, 10 μ c. of ¹⁴C-algae hydrolysate (1.4 mc./mg) (New England Nuclear Corporation, Boston, Massachusetts) were added to each culture flask. The

cultures were incubated for 6 h at 37°C in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. Following incubation, the contents of the flasks were frozen and thawed once, centrifuged, and the supernatant dialysed against four changes of 0.14 M sodium chloride over a 48-h period. The dialysand was concentra-

Fig. 2. A, Photograph of results of immunoelectrophoretic analysis of tissue culture fluid and serum using monospecific antiserum. B, Autoradiograph of same slide

ted 20-fold by dehydration with 'Aquacide' (Calbiochem, Los Angeles, California). The concentrated culture fluid was analysed by immunoelectrophoresis in 0.05 M veronal buffer, pH 8.2, according to Scheidegger⁷, using a 1:1 dilution of serum from the donor rat as a protein carrier. After washing and drying the slides, autoradiography was carried out by the method of Hochwald *et al.*⁴, using Kodak 'Royal Ortho' sheet film and an exposure time of 2 weeks. The preparation of the anti-whole serum and the specific antiserum in rabbits has already been described^{8,9}.

Fig. 1A shows the photograph of the results of the immunoelectrophoretic analyses of the concentrated tissue culture fluid and carrier proteins. Fig. 1B is an autoradiograph of the same slide. Radioactive labelling of the α_1 -glycoprotein (Darcy) indicative of synthesis by the liver was unequivocally demonstrated. Also of interest was the incorporation of radioactivity into 12 other proteins. These are depicted schematically and designated according to a system of nomenclature previously reported⁸. Results of similar analyses using the monospecific antiserum are presented in Figs. 2A and B, respectively. These results provide independent confirmation of the findings shown in Fig. 1 with respect to the α_1 -glycoprotein (Darcy).

Fig. 1. A, Photograph and schematic representation of results of immunoelectrophoretic analysis of mixture of tissue culture fluid and carrier serum proteins from donor rat. B, Photograph and schematic depiction of autoradiograph of same slide

A New Bisalbuminaemic Family

THIS communication reports the first bisalbuminaemic family found in France. As the family tree shows (Fig. 1), the anomaly seems to be due to a co-dominant, autosomal

Fig. 1. The family tree. Positive cases, black spotted circles; negative cases, blank circles; cases not examined, broken circles

Fig. 2. Cellulose-acetate strip electrophoretogram of a positive case

Fig. 3. Free electrophoresis of one positive case

Fig. 4. Immunoelectrophoretic analysis of a positive case. Development with equine anti-human serum. The serum of the subject is diluted to 1/30th; so the α_1 -globulin traits are distinctly separated from the albumin trait

allele at the albumin locus; we have confirmed this general conclusion. The separation of the two albumins was excellent on a cellulose acetate strip (Fig. 2) and shows, without any doubt, that the anomalous albumin is the slower one. But free electrophoresis using a Perkin-Elmer apparatus disclosed only a weak 'shoulder' on the cathodic side of the albumin band (Fig. 3). Immunoelectrophoresis and the Ouchterlony test using anti-human serum, or specific anti-human albumin serum, did not show any difference between the two albumins (Fig. 4). The anomalous albumin, evaluated after dye elution on the cellulose acetate strip, represents in all cases about 40 per cent of the total albumin. The subjects presenting the anomalous trait were normal in all other respects.

A recent check disclosed that about fifteen bisalbuminaemic families have been reported in the literature¹. Nearly always, the anomalous albumin demonstrated the same characters. Only Tarnoky *et al.*¹ and Wieme² conclude that the anomalous albumin was the faster-moving one. But in these cases, due perhaps to technical imperfections, the separation of the two bands was very poor and so any comparison with normal sera is not likely to lead to any clear-cut conclusion. We agree with Harris³ that bisalbuminaemia could be a unique hereditary trait. Taking into account the chemical results obtained by Gitlin *et al.*⁴, it may be attributed to a mutation involving a specific point in the albumin polypeptide chain.

IMMUNOLOGY

Bone Marrow as the Major Source of Potential Immunologically Competent Cells in the Adult Mouse

PREVIOUS work from this laboratory¹⁻⁴ has suggested that immunologically competent cells are derived from foetal liver during embryonic life and that their 'functional maturation', or proliferation, or both, is dependent on the residence of these cells in thymic tissues. The source of these lymphoid precursor cells during adult life is not known. Using chromosomally marked cells, it has been shown, however, that when cell suspensions of various adult lymphoid tissues are injected into lethally irradiated mice only those cells derived from bone marrow are found in the thymus of the host in significant numbers; while the cells from other lymphoid tissues readily proliferate in the peripheral lymphoid tissues of the host, they are only rarely found in the thymus⁵. In experiments involving the restoration of immunological competence in lethally irradiated thymectomized adult mice, Miller *et al.*⁶ concluded that "marrow cell suspensions lack adequate numbers of immunologically competent cells but contain precursor cells" which mature under the influence of the thymus. Furthermore, Feldman and Globerson⁷ have reported work which suggests that the immunological reactivity manifested by thymectomized mice which have been lethally irradiated, but protected with bone marrow cells and restored to immunological competence with an allogeneic thymic graft, may be due to the donor marrow cells rather than to cells from the thymic graft. Taken together, these results suggest that bone marrow is the source of potential immunologically competent cells in the adult. It is the purpose of this communication to present data which suggest that bone marrow may be the major, or perhaps sole, source of lymphoid precursor cells in the adult mouse.

The presence of potential immunologically competent cells was demonstrated by a modified parental- F_1 hybrid, 'graft-versus-host', method. When adult lymphoid tissues from a homozygous donor are injected into sub-lethally irradiated F_1 hybrids, one parental strain of which is identical to that of the donor, a significant number of deaths will occur as a result of an immunological reaction by the donor cells against the transplantation antigens of the second parent of the hybrid. Survivors can be obtained, however, by transplanting small numbers of donor cells. If it is postulated that mature immunologically competent cells are consumed, that is, 'allergic death', during the course of this graft-versus-host reaction⁸, then surviving mice which were injected with mature cells only should no longer contain lymphoid cells of donor origin. On the other hand, immature lymphoid cells (potential immunologically competent cells) are incapable of responding to the foreign antigens of the host¹⁻⁴ and, as was found with foetal liver cells¹⁻⁴, should survive in the primary host in significant numbers. On this basis, graded numbers of cells from various lymphoid tissues of adult homozygous mice were injected into groups of sub-lethally irradiated F_1 hybrids. The spleen and lymph node cells and cells from the thymus of the mice which survived 60 days were then injected into a second F_1 hybrid (one parental strain identical to that of the donor but the second parental strain differing from the second parent of the first F_1 hybrid). Death of the secondary recipients was taken as evidence for the presence of lymphoid precursor cells in the original inoculum. The experimental design may be summarized as follows:

The lymphoid organs used were spleen and lymph node, thymus, bone marrow, liver and peripheral blood. These tissues were obtained from 12-14-week-old A/HeJ male and female mice. Where necessary, the tissues were gently disrupted in a glass homogenizer, and the cells were suspended in Tyrode's solution. Graded numbers of viable nucleated cells were injected into ($BALB/c \times A$) F_1 mice which had just received 500-rad whole-body X-radiation. After 60 days, the survivors were killed individually; their spleen and lymph nodes and thymus were gently disrupted, and the resultant cell suspensions were injected into one thymus) or two (spleen and lymph node) sub-lethally irradiated (500 rads) ($C57L \times A$) F_1 mice. In addition, lymphoid tissues were taken from adult $CBA-T6T6$ mice and, as already described, injected into sub-lethally irradiated ($C57BL/10 \times CBA-T6T6$) F_1 mice. After 80 days these mice were killed and their tissues (thymus, lymph node, spleen and bone marrow) prepared for chromosome analyses⁹. $CBA-T6T6$ mice contain two distinct minute chromosomes; their presence among the metaphase plates of the F_1 hybrid host would provide direct evidence of the survival of the donor cells.

Table 1 SIXTY-DAY MORTALITY IN SUB-LETHALLY X-IRRADIATED (500 RADS) PRIMARY AND SECONDARY F_1 HYBRID RECIPIENTS OF ADULT LYMPHOID TISSUES. THE SECONDARY HOSTS RECEIVED EITHER SPLEEN AND LYMPH NODES OR THYMUS FROM THE PRIMARY RECIPIENTS

Adult tissue injected	No. of cells $\times 10^6$	60-day mortality (No./total)		
		Primary hosts	Spleen + lymph node	Thymus
Spleen and lymph node	0.9	7/10	0/6	0/3
	1.0	8/15	1/10	
	2.5	10/10		
Thymus	2.1	0/10	0/20	
	2.5	3/10	0/8	
	7.0	0/10	4/20	1/10
Peripheral blood	0.2	1/10	0/18	0/10
	0.2	8/10	0/4	
	0.5	9/10	0/2	0/1
	1.0	8/10	0/4	
Bone marrow	2.1	0/10	5/20	
	6.0	0/10	11/20	0/10
	7.0	3/10	9/14	
Liver	1/40 adult liver	0/10	0/14	0/7
None	1/4 "	3/10	0/20	0/10
		0/36	3/49	0/17

Table 2. $CBA-T6T6$ CELLS IN THE LYMPHOID TISSUES OF SUB-LETHALLY X-IRRADIATED ($C57BL/10 \times CBA-T6T6$) F_1 HOSTS 80 DAYS AFTER THE INTRAPERITONEAL INJECTION OF VARIOUS ADULT $CBA-T6T6$ LYMPHOID TISSUES

Adult tissue injected	No. of cells $\times 10^6$	$CBA-T6T6$ cells/total mitotic figures			
		Bone marrow	Spleen	Lymph nodes	Thymus
Spleen and lymph nodes	1.0	0/50	0/50	* 23/69	0/50
Thymus	3.0	* 23/200	0/77	* 21/118	0/39
Peripheral blood	0.3	* 23/125	0/38	0/14	0/28
Bone marrow	7.0	2/34	1/21	2/15	3/23
Liver	8.0	* 24/125	* 21/50	* 21/50	0/50

* These mitotic figures contained one typical $T6$ minute chromosome and another small somewhat atypical minute chromosome. As there was no other evidence of radiation damage to the chromosomes in these plates, they were classified as possible $T6T6$.

A significant number of deaths occurred among the secondary hosts only when they had received spleen cells from mice which had been injected with adult bone marrow (Table 1). There were no deaths among the mice which received thymus cells from the primary hosts. Further, the $CBA-T6T6$ chromosomal marker was found consistently and unequivocally only in those mice which had received bone marrow cells (Table 2). While there were cells which might have been of $CBA-T6T6$ origin in the peripheral lymphoid tissues of mice given other adult lymphoid tissues, $CBA-T6T6$ cells were found in the thymus of the host only when bone marrow had been given.

While it is known that bone marrow contains relatively few mature immunologically competent cells, taken together, these results, based both on functional and on morphological criteria, support the thesis that bone marrow serves the adult mouse

as a major, or perhaps as the sole, source of potential immunologically competent cells. Furthermore, these results imply that the thymus is not the source of lymphoid precursor cells, but rather that it provides a critical site for the maturation of these cells.

Immunogenic Activity of Lipids of *M. tuberculosis*

LIPIDS of mycobacteria are known to be immunogenically active components of tubercle bacilli¹. First of all, it was surprising that mycobacteria contain lipids up to 35 per cent of their dry weight². This fact did not escape the notice of immunologists. It seemed highly improbable that this fraction of the mycobacteria should not contain antigens or—more likely—haptens. Since alcohol-soluble lipids form stable aqueous suspensions, they can be examined relatively easily. However, the majority of mycobacterial lipids consists of waxes which form no stable aqueous suspensions and usually exhibit an anti-complementary action. By means of a newly developed microprecipitin technique³ it became possible to investigate all kinds of lipids, independently from their solubility in organic solvents.

The extracts were prepared according to the method described by Aebi *et al.*⁴. Seven fractions were obtained: fats, phosphatides, waxes A, B, C (cord-factor) and D, and firmly bound lipids. It has been shown that only three of these fractions contained compounds capable of combining with antibody⁵. These fractions were the phosphatides and the waxes B and D. All other lipids were serologically inactive. The phosphatides and the waxes B showed no strain-specificity. However, the wax D might have strain-specificity⁶. It is interesting to note that C (cord-factor), the toxic substance of mycobacteria, did not combine with antibody. Consequently, antitoxic immunity might be impossible.

The waxes B did not always contain serologically active substances. This might be due to minor variations of the fractionating procedures. The active substance of the phosphatide fraction consisted of phospholipids, which contained inositol and 2–5 mannoses⁷. After saponification, phospholipids gave no precipitation, while with the water-soluble part of the wax D a weak precipitation could be observed. (Pure phospholipids and many other fractions were kindly supplied by Prof. E. Lederer and Mme. E. Vilkas, Gif-sur-Yvette, France.) The hydrophobic part of the molecules (for example, mycolic acid) had no antibody-combining capacity. Evidence available at present indicates that the determinant groups of lipid haptens are hydrophilic.

The immunogenic activity of mycobacterial lipids was experimentally tested in guinea-pigs. Groups of 10 guinea-pigs each of mixed colour and sex, approximately 500 grams in weight, were used. Groups of guinea-pigs were inoculated subcutaneously with phosphatides (0.5 mg phosphatide per ml.), wax B (0.25 mg wax B per ml.), wax D (0.5 mg wax D per ml.) with and without bovine serum albumin (0.5 mg/ml.) in 1 ml. of Freund's adjuvant. Control animals received Freund's adjuvant alone (1 ml., 'Arlacel A', Paraffinöl, Merck, saline), heat inactivated bacteria (1 mg/ml.) of the strain H 37 Rv, and living bacteria of the BCG strain (1 mg/ml.).

Fig. 1. Survival-time of guinea-pigs (wax D). Day 0 represents the day of challenge (4 months after immunization)

In order to avoid non-specific reactions, the animals were infected with 1 mg of virulent bacteria of the strain H 37 Rv 4 months after immunization. They were observed for 160 days. After that period all control animals inoculated with Freund's adjuvant alone died. The tuberculosis was diagnosed macroscopically.

Fig. 1 shows the results of a typical experiment. The survival time of the control group and of the test group (wax D) did not differ significantly. The results of the other control experiments (heat-killed H 37 Rv and BCG) indicated a partial protection against tuberculosis; the difference between the survival time of these groups is significant. The phosphatides, waxes B and waxes D failed to provide measurable immunity, even when administered together with bovine serum albumin.

PATHOLOGY

Cutaneous Elastin in Ehlers-Danlos Syndrome

EHLERS-DANLOS syndrome (cutis hyperelastica, india-rubber skin), a rare heritable generalized disorder of the connective tissues, is characterized by hyperextensibility of the skin, hyperlaxity of the joints, fragility of the skin, and, not infrequently, by one or a combination of such internal manifestations as cardiac anomalies, dissecting aneurysm of the aorta and diaphragmatic hernia¹. Previous investigations directed towards identifying the fundamental defect in the connective tissues, using the methods of light and electron microscopy, have led to contradictory results. Many investigators have described an increase in the amount of elastin in the corium while others have observed a normal or even a decreased amount of elastin¹. Similar controversy exists over the possibility that the collagen is either quantitatively or qualitatively abnormal in this disease^{1,2}. The purpose of the work reported here was to isolate elastin quantitatively from the skin of patients with this disease and from the skin of normal, control subjects, and to examine chemically the purified elastin isolated from these two sources.

Normal human skin was obtained as necropsy specimens from the thighs of Caucasian females. The skin from four female patients with Ehlers-Danlos syndrome (E-D) was obtained as biopsy material from the same site as in

the control subjects. All test subjects demonstrated the complete syndrome. Hair and subcutaneous fat were removed mechanically as completely as was possible. The skin, after being cut into small pieces and frozen in liquid nitrogen, was crushed by percussion in a small metal mill. The powdered tissue was weighed both before and after drying in a desiccator over phosphorus pentoxide at room temperature. When the weight of the tissue became constant it was treated with a 5.0 M sodium chloride solution at 4° C for 48 h. After removal of the salt by washing with water, the material was treated with acetone for 72 h. The dried, defatted tissue was autoclaved in a 2 per cent aqueous solution of acetic acid (50 ml./g of dried tissue) at 15 lb./in.² for 2 h. The remaining insoluble material, washed free of acetic acid, was exposed to a 0.1 N sodium hydroxide solution for 15 min at 98°. The treatment with sodium hydroxide was repeated for a second 15-min interval using a fresh aliquot of alkali. The insoluble product, after suitable washing and drying, was weighed and designated purified elastin. Amino-acid analyses were carried out on the Technicon auto-analyser after hydrolysis of the purified elastin with 6 N hydrochloric acid for 24 h.

The elastin content of skin from patients with E-D and from normal subjects was essentially the same (Table 1). The 40-year-old patient with E-D had demonstrated marked clinical improvement in the elasticity of her skin over the years, and at the time the biopsy was taken the skin was much less extensible than that of her 9-year-old daughter with the disease. The observation that the elastin content of their respective skin biopsies from corresponding sites was so similar, suggested that improvement in the condition of the skin with age was independent of the amount of elastin present. It was of interest that the elastin content of the skin from the knee and from the thigh of one of the patients was almost the same, as it has been suggested that, in this disease, excessive and repeated stretching of the skin at articular sites might stimulate the production of excessive amounts of elastin¹. Germane to our biochemical findings was the observation made with the electron microscope that teased preparations of skin from all four patients with E-D and from normal control subjects demonstrated similar amounts of elastin in the skin of test and control subjects. This observation conflicts with the findings of an early paper by Tunbridge *et al.*² but confirms the work of Jansen⁴. We found no consistent difference in the amount of elastica staining material seen by light microscopy in the skins of patients with E-D and of normal individuals. The amount of such material varied greatly even in a given case and depended to a large extent on the exact angle at which the tissue was cut.

The amino-acid composition of elastin from the skin of patients with E-D and from that of normal subjects was almost identical. Typical results are shown in Table 2. The polyfunctional, isomeric amino-acids, desmosine and isodesmosine⁵, involved in the cross-linking of the polypeptide chains found in the elastin of aorta and bovine ligamentum nuchae also appeared to be present in the elastin of human skin and in similar amounts as in elastin from aorta and ligament. The elastin in the skin of patients with E-D contained a normal amount of desmo-

Table 2. AMINO-ACID COMPOSITION OF ELASTIN FROM NORMAL SKIN AND FROM A PATIENT WITH EHLERS-DANLOS SYNDROME

Amino-acid	Elastin from skin of normal subject* g amino-acid/100 g protein	Elastin from skin of patient with E-D* g amino-acid/100 g protein

* The normal subject is the one designated N 15 while the patient with E-D is the one identified as E-D 15.

sine and isodesmosine. As the lysine content of elastin varies inversely with the desmosine content⁶, the normal lysine content of the skin elastin from these patients provided further evidence that the elastin in E-D was normally cross-linked.

However, another type of cross-linking in elastin, one involving sialic acid, has been described⁷. This type of cross-linking was not examined by us, as the small quantity of elastin isolated from the biopsy material was insufficient to permit us to measure quantitatively the minute sialic acid content of purified elastin.

As the quantity, amino-acid composition and desmosine cross-linking of elastin in the skin of these patients was normal, one can conclude that elastin is most probably not the defective element in the connective tissues in E-D. The observation made by Rollhäuser that the tensile strength of the skin of these patients was only approximately 1/5 that of normal skin⁸ makes it even more likely that the fundamental defect does not lie in the elastin. The tensile strength of skin is attributable, for the most part, to the collagen present by virtue of the quantity (70 per cent of the dry weight of skin) and nature of its fibres⁹. Any marked decrease in tensile strength in skin is thus more likely to be secondary to a change in the quantity and/or quality of the collagen or in factors such as water and polysaccharide content which influence collagen strength, than to abnormalities in the elastin. On theoretical grounds alone, it is difficult to understand how an increase in the elastin content of skin without a proportional decrease in collagen could account for the observed increased extensibility of the skin. The hyperlaxity of non-cutaneous structures in this disease, such as fascia and joint capsules composed almost wholly of collagen with no elastin, further supports the hypothesis that the collagen rather than elastin is defective in E-D.

We thank Dr. R. Reed for doing the electron microscopy, Miss Rosalind Slater for the preparation of specimens for light microscopy, Dr. L. Rodén for the amino-acid analyses and Prof. R. E. Tunbridge for his assistance in obtaining the pathological skin specimens

knee	121.6	2.81
E-D 40	120.0	2.50
E-D 9	153.7	2.63

* N designates a normal subject while E-D represents a patient with Ehlers-Danlos syndrome. The figure following the letters gives the age of the subject. All subjects were female and except in E-D 24 the skin samples were removed only from the lateral aspect of the midthigh.

Prevention of Cholesterol-induced Cholelithiasis by Neomycin

RABBITS receiving 0.25–1 per cent dietary cholesterol (5 α -cholestan-3 β -ol) for 3–6 weeks develop gall-stones which have been shown to consist predominantly of calcium and sodium glycoallodeoxycholate (3 α -, 12 α -dihydroxy-5 α -cholanoic acid)^{1,2}. Gall-stone formation in cholesterol-fed rabbits has been postulated to occur as follows: Cholesterol is absorbed from the intestinal tract of the rabbit and is transported to the liver where some of the cholesterol is metabolized to allocholic acid (3 α -, 7 α -, 12 α -trihydroxy-5 α -cholanoic acid). The latter is conjugated with glycine, excreted into the bile and eventually reaches the intestinal tract where it is hydrolysed and dehydroxylated by the intestinal bacterial flora to form allodeoxycholic acid (3 α -, 12 α -dihydroxy-5 α -cholanoic acid). This dihydroxy bile acid is reabsorbed and returns to the liver where it is conjugated with glycine and re-excreted into the bile as glycoallodeoxycholate. The mixed calcium and sodium salt of the latter is relatively insoluble in bile², and therefore is thought to be the cause of gall-stones in cholesterol-fed rabbits. In contrast, the calcium-sodium salt of glycodeoxycholate is relatively soluble in aqueous media.

Since a major step in the formation of gall-stones appears to be the bacterial 7-dehydroxylation of allocholic acid, it is reasonable to assume that the reduction or elimination of the bacteria responsible for the conversion might interfere with gall-stone formation. Because of its well-known anti-microbial effect against the normal intestinal flora, neomycin seemed to be a suitable antibiotic for testing this hypothesis.

The experiments were carried out as follows. Two groups of six rabbits each were fed 1 per cent cholesterol (kindly donated by the Schering Corporation) in their diet of Purina rabbit chow pellets for a period of four weeks. One group was given drinking water containing 0.5 per cent (w/v) neomycin sulphate (kindly donated by E. R. Squibb and Sons). The control animals received ordinary water. During the experimental period food and water intake was measured daily, and the animals were weighed weekly. None of the animals suffered any diarrhoea. Specimens of faeces were collected at the start of the experiment, at the end of two weeks and on the final day of experiment. The number of coliform organisms per gram dry faeces was determined using eosin-methylene blue plates³ and lactose broth in the five-tube method³. The animals were killed at the end of four weeks and autopsies were performed. The contents of the gall bladders, either as liquid bile or gall-stones, and samples of the liver were collected from each animal; the livers were analysed for total sterol and cholesterol⁴. Gall-stones, when present, were dried, weighed and analysed for allo (5 α -) and normal (5 β -) bile acids². Bile, when present, was treated with hot ethanol to precipitate the proteins. The ethanol supernatant was analysed for bile acids by the methods applied to the gall-stones. The results are summarized in Table 1.

None of the animals that received cholesterol and neomycin developed gall-stones. In contrast, all the animals that received cholesterol alone developed gall-stones; the average dry weight of the stones was 211 mg

per animal. The neomycin-treated group ate 16 per cent less food and drank 28 per cent less water than the cholesterol group, and, as a result, the rabbits in the neomycin-cholesterol group gained only 150 g each in four weeks compared with 300 g gained by the cholesterol group. However, all animals appeared healthy throughout the experiment. The average food intake of 75 g/day in the neomycin-cholesterol group corresponded to the ingestion of 750 mg of cholesterol daily which should have been adequate to induce cholelithiasis^{1,5}.

Bacteriological analysis of the faeces disclosed that the administration of neomycin generally resulted in an almost complete abolition of the coliform organisms. However, in one animal there was a thousand-fold increase of coliform bacteria resistant to neomycin, but, like the other animals of the group, it did not develop gall-stones.

Histological examination of the gall bladder revealed little difference between the two groups. One small collection of inflammatory cells was seen in two of the six animals with cholelithiasis. Necrosis, ulceration of the mucosal surface, oedema, or marked inflammation were not observed. These findings confirm those of Borgstrom *et al.*⁶ and suggest that cholesterol-induced cholelithiasis can occur without antecedent injury to the wall of the gall bladder. No abnormalities were found in other organs.

The average liver total sterol content and the relative proportion of cholesterol to cholesterol in the liver sterols were lower in the neomycin-treated group than in the control group which received no antibiotic. However, the results listed in Table 1 show that there was considerable overlap among the two groups. For example, one rabbit in the neomycin group (which had no gall-stones) had a higher proportion of cholesterol in its liver sterol fraction than any of the controls.

Analysis of bile and gall-stones by thin-layer and gas-liquid chromatography² revealed the following: (1) The gall-stones of the rabbits receiving dietary cholesterol but no antibiotic consisted of glycoallodeoxycholate (75 per cent), and small amounts of glycodeoxycholate and glycocholates, as described previously². (2) The bile of the animals treated with cholesterol plus neomycin (in which gall-stones were absent) contained only traces of glycoallodeoxycholate. Glycodeoxycholate and glycocholate were present in approximately equal proportions together with lesser amounts of glycoallocholate and unidentified cholanoic acids.

The oral administration of neomycin to cholesterol-fed rabbits prevented gall-stone formation because it reduced the biliary concentration of glycoallodeoxycholic acid, which is the major component of cholesterol-induced gall-stones. The absence of allodeoxycholate from the bile of rabbits treated with cholesterol plus neomycin is thought to be due to the antibiotic action of neomycin on the intestinal micro-organisms which carry out the 7-dehydroxylation of allocholic acid.

These findings are compatible with the following possibilities: (a) the bacteria acting on 5 α -(allo) bile acids are different from those acting on the normal 5 β -bile acids; (b) the bacteria acting on 5 α -(allo) bile acids are extraordinarily sensitive to neomycin; (c) neomycin, in reducing the bacterial flora, reduces the amount of enzyme available for the 7-dehydroxylation of the bile acids. If the enzyme has a greater affinity for the normal 5 β -bile acids, little

Table 1. EFFECT OF NEOMYCIN ON THE BIOLOGICAL DISPOSITION OF CHOLESTANOL

Regimen	Food intake (g/day)	Liquid intake (ml/day)	Average weight of rabbits		Average dry weight of gall-stones (mg)	Liver sterols, average

RADIOBIOLOGY

In vitro Effect of Gamma-radiation on Different Cholinesterase Preparations

THE interaction of high-energy radiation with proteins has received a great deal of attention and in the past few years much has been published on this subject.

Although the interactions with proteins undoubtedly play a vital part, the biochemical effects are frequently ambiguous, and this is the case in the results described for the variation of the cholinesterase activity after γ -irradiation.

Experiments were designed to investigate the *in vitro* effect of γ -rays on cholinesterase from various sources and of differing grades of purity. Irradiations were performed at 18° C in a thermostatically controlled cylindrical 2,000-c. cobalt-60 source. The dose-rate used was 2.5×10^5 r./h. Ten samples were simultaneously irradiated in sealed glass ampoules with a head space of 6 ml., containing air. Controls were handled in the same fashion, but they were not placed within the cobalt source. Dosimetry for experiments was performed by the method of Weiss¹.

The preparations exposed to γ -radiation were: (1) bovine red blood cell cholinesterase (Sigma Chemical Co.); (2) common fly-brain cholinesterase preparations at different stages of purification. These stages were: whole heads; homogenate; and a purified fraction. Heads were collected by the Moorefield method² and the homogenate had 60 mg of fresh tissue per ml. distilled water.

The purified fraction was obtained according to the following method: a homogenate was adjusted to pH 8.5 with 0.1 N sodium hydroxide and allowed to stand 20 h at 5° C, after which time it was centrifuged in the cold at 100,000*g* for 30 min. The supernatant was brought to 41 per cent saturation with solid ammonium sulphate and centrifuged again at 15,000*g* for 15 min. The supernatant was brought to 78 per cent saturation. Centrifugation at 15,000*g* yields a purified cholinesterase preparation which was used as a suspension in distilled water³.

The enzymatic activities of the samples were controlled within 1 h of irradiation. Cholinesterase activity was measured potentiometrically using as substrate a solution of 0.5 M sodium chloride-0.04 M magnesium chloride-

Fig. 1 pH decrease (ΔpH) following several doses of γ -radiation. \times , Whole heads; \bullet , purified samples of common fly brain cholinesterase; \circ , red cell cholinesterase

Fig. 2 Effect of irradiation on the activity of cholinesterase preparations. \times , Whole heads; \bullet , homogenate; \bullet , purified preparation, \circ , red cells

0.002 M acetylcholine bromide in 0.5 M phosphate buffer pH 7 and 38° C. The acetic acid liberated was automatically determined by titration with 0.005 N sodium hydroxide. Enzymatic activity was expressed as ml. consumed alkali per min.

Fig. 1 gives the extent to which the pH of the samples was affected by the γ -irradiation.

Experimental results were evaluated by plotting the percentage of the remaining enzymatic activity as a function of irradiation dose (Fig. 2).

From these results it is clear that the more purified the samples were, the more was the inactivating effect of the irradiation. In the cholinesterase preparations from common fly, the order of inactivation was: purified sample > homogenate > whole heads. Assays carried out with red blood cells and cholinesterase from the electric eel (Sigma Chemical Co.) showed a high grade of inactivation (100 per cent of inactivation in a 50 u/ml. solution receiving a 10^6 r. dose). Some data on the nature of this radio-resistance were obtained. The homogenate completely lost its cholinesterase activity by heating it at 100° C for 2 min; when the filtrate was added to the purified sample, a clear protection could be shown ranging from 80 to 40 per cent. Nevertheless, the supernatant from the homogenate precipitated by addition of trichloroacetic acid did not show any protective properties.

BIOLOGY

Evolutionary Tendency of Relative Growth in Arthropods and Man

IN a series of investigations dealing with the comparative studies of relative growth in various groups of arthropods and man¹⁻⁷ I have confirmed a tendency that the growth ratios of rapidly growing parts of the body tend to be more similar than those of slowly growing parts when two or more closely related forms (such as geographically isolated populations, subspecies, parthenogenetic and bisexual strains of the same arthropod species, interspecific-hybrid and very closely related species in arthropods, Negro and Caucasian children) are compared. This indicates that in incipient stages of structural divergence during evolution the slowly growing parts would tend to be more affected than rapidly growing parts.

This tendency appears, *a priori*, to be possible (Fig. 1). If the growth ratios of rapidly growing parts differ greatly between very closely related forms, the final (adult) sizes and shapes of these parts would tend to be greatly different, and these forms would scarcely appear to be closely related. Therefore, the growth ratios of rapidly growing parts are expected to be similar among very closely related forms. In the comparison of Negro and Caucasian children's growth (see ref. 9), the growth ratios of five out of six most rapidly growing parts (bitrochanteric breadth, upper arm length, lower arm length, thigh length, lower-leg length) are nearly identical between the two races. The same tendency may well hold true in similar comparisons in other groups of animals besides the arthropods and man.

If the growth ratios of slowly growing parts are considerably different (Fig. 1) while those of rapidly growing parts remain much the same, the adults of the closely related forms would tend to look similar in general size

Fig. 1. A simplified model showing the difference in adult sizes in rapidly and slowly growing parts between two closely related species A and B. K is the growth ratio of allometric growth equation. The growth ratios of both rapidly and slowly growing parts in species B are assumed to be 80 per cent of the corresponding parts in species A. The final difference between rapidly growing parts here is five times greater than that between slowly growing parts.

and shape while showing minor yet distinct structural divergences. This is exactly what taxonomists would expect to see in comparing closely related forms. This tendency has been abundantly proved in several groups of arthropods and the human races.

The modification of growth ratios of rapidly growing parts would tend to lead to the divergence at higher taxonomic units. The evolution of relative growth at higher levels of taxonomic unit in arthropods has been discussed earlier⁸.

Phytotoxin Production by *Verticillium albo-atrum* Reinke et Berthold

THE physiology of vascular wilt diseases caused by *Fusarium* and *Verticillium* species has received considerable attention during recent years¹⁻⁴. Of these organisms, less work has been carried out on *Verticillium*, and certain aspects of the disease syndrome caused by this fungus are not fully understood. Studies on symptom initiation have for the most part been concerned with the production by the fungus of pectolytic enzymes⁵⁻¹¹. Numerous authors have mentioned the possible role of toxins in disease initiation, but little supporting experimental evidence has so far been produced. Moreover, from the lack of a precise definition, the toxins of some authors^{12,13} might include extracellular pectolytic enzymes. Porter and Green¹⁴ and Green¹⁵ published the first authentic accounts of toxins produced in *Verticillium* culture filtrates. Bioassay of nearly all suspected disease-inducing agencies has been on cut shoots, in an attempt to simulate wilt conditions, in the naturally infected plant. In Nature, however, wilting symptoms usually develop after about 14 days, and experiments in this laboratory have shown that, in the case of seedling infection, growth inhibition rather than overall wilting is a more valid symptom of disease. Up to five weeks after infection in these plants wilting is a gradual basipetal desiccation while the leaf area of apparently turgid leaves is reduced by 80 per cent. This symptom is quite different from the general collapse of turgor common in mature infected plants and may be independent of it.

Experiments reported in this communication represent the preliminary findings of an attempt to isolate from *Verticillium* culture filtrates a growth-inhibiting substance other than a large protein molecule which could account for some of the naturally occurring stunting symptoms. A virulent strain of *V. albo-atrum* Reinke et Berth. was used, originally isolated from a wilting tomato plant by Dr. H. H. Glasscock of the National Agricultural Advisory Services, Wye, Kent. Still cultures consisting of 300 ml. of 'Seitz'-filtered tomato xylem exudate, supplemented with 1 per cent sucrose in horizontally placed 1-l. Thompson flasks, were grown at 22° C for 21 days in a dark incubator. The xylem exudate collected from tomato, cultivar 'Victory', had previously been stored at -20° C until required. Culture solutions were filtered once through several layers of fine cheese muslin and then twice through Whatman No. 1 paper. The filtrate was centrifuged at 16,000g for 15 min at 5° C and then reduced to small volume in a cyclone evaporator at 23° ± 5° C. The pH of the filtrate was adjusted to 2.5 with N hydrochloric

acid and partitioned against three equal volumes of 'AnalaR' redistilled ethyl acetate. The individual solvent phases were extracted on the counter-current principle with a single equal volume of 5 per cent sodium bicarbonate (pH 8.2). The residual solvent phases were bulked and regarded as the neutral fraction and the aqueous alkaline phase was adjusted to pH 2.5 with 4 N hydrochloric acid and extracted as before with ethyl acetate, this latter phase being regarded as the acidic fraction. The original aqueous phase after the preliminary partition was adjusted to pH 8.2 with an excess of solid sodium bicarbonate and extracted with ethyl acetate as before. The extracts were dried by freezing out the water at -20°C and then reducing to dryness at $23^{\circ} \pm 5^{\circ}\text{C}$. The three dry or oily residues were dissolved in a minimal quantity of ethyl acetate and chromatographed on Whatman 3 MM solvent-washed paper for about 15 h with the solvent isopropanol-ammonia-water, 10:1:1 v/v descending. Active regions were eluted and rechromatographed on Whatman No. 1 paper and run with the same solvent ascending. Papers were dried and segmented into 10 strips parallel with the origin, each about 6.4×2 cm corresponding to an R_F value of 0.1. These were eluted with 1.5 ml. M/100 phosphate citrate buffer and incubated with 1 cm segments of etiolated tomato hypocotyl tissue in a test designed to measure growth inhibitors¹⁶. The final lengths of extended hypocotyl

segments after 48 h incubation corresponding to each R_F value were expressed as a percentage of the control segments incubated in buffer only. Fig. 1 illustrates the results of assays of acidic, basic and neutral extracts of culture filtrates. In the acidic fraction, two large peaks of inhibition are evident at R_F 's 0.0-0.2 and 0.3-0.6, each of about 30 per cent of the control values. Tissue in these tubes was brown and flaccid and incapable of further growth when washed and placed in pure buffer. In the assay of the basic fraction, inhibition was detected at R_F 0.8-0.9 with a peak at R_F 0.85. A single peak was seen similar to the basic at R_F 0.85 in the histogram of the neutral fraction with, in addition, a minor peak at R_F 0.35. Tests with various substances using the foregoing method of extraction have shown that weakly acidic substances may partition imperfectly between ethyl acetate and water at pH 2.5 and very small quantities of acidic substances may escape into the neutral fraction. The neutral substance at R_F 0.35 might therefore represent escaped acidic material.

Wilting tests carried out on cut shoots of six-week-old tomato plants cultivar 'Potentate' using aqueous eluates of chromatographed acidic, basic and neutral extracts showed that the acidic extracts were not capable of inducing wilt symptoms. Neutral and basic extracts, however, both induced wilt in the tomato shoots only in the eluate corresponding to R_F 0.75. The neutral eluate at R_F 0.35 was inactive as a wilt inducer.

These results from *in vitro* studies on *Verticillium albo-atrum* suggest that wilting and stunting in infected plants may result from different causes. It is unlikely that the disease syndrome could result from a single causative factor, and indeed, by the time of symptom appearance, disordered host metabolism, quite apart from the initiating effect, may account for a great part of the visible symptoms.

Substances such as those described in this communication, however, could be instrumental in initiating pathogenesis in *Verticillium*-infected tomato plants.

Establishment of a Pure Infection of the Nematode *Ostertagia circumcincta* in the Sheep

THE four smaller nematode parasites of the abomasum of the sheep, *Ostertagia circumcincta*, *O. trifurcata*, *Teladorsagia davidi* and *O. mentulata*, commonly occur as mixed infections. A search of the literature revealed only three instances¹⁻³ in which it was claimed that pure infections of *O. circumcincta* had been used. In all three, the evidence on which the claim was based was not provided. However, Horak (personal communication) states of his pure strain that he has "examined thousands of male worms and all have been *O. circumcincta*". In Australia,

and elsewhere, mixed infections have been reported to be the common finding by Gordon (personal communication); Sommerville¹; Armstrong⁵ in New Zealand; Todd⁶ in the United States; Parnell⁷ in Great Britain, the proportions of the different species being between 80 and 90 per cent *O. circumcincta*^{4,8}, and the remainder one or a mixture of the others, the predominant species being *O. trifurcata*.

In an examination of the immunological reactions of sheep to ostertagiosis, and possible antigenic differences between the four species and of their validity as distinct species, an attempt was made to establish a pure infection of *O. circumcincta*.

Morphologically, the four species resemble each other so closely that females cannot be differentiated; but males are distinguishable by the length of their spicules together with certain less prominent differences in structure of their genital cone. On the basis of spicule length the nematodes fall into three groups—long spicules (*O. mentulata*), medium length spicules (*O. circumcincta*) and short spicules (*T. daviani* and *O. trifurcata*).

Three hundred living adult *O. circumcincta* males were collected individually from the abomasal contents of freshly killed sheep, using a dissecting microscope, and placed via a laparotomy incision in the abomasum of a worm-free lamb together with 300 fourth-stage mixed larval females of unidentifiable species. These latter came from a sheep in which 88 per cent of the males were *O. circumcincta* and 12 per cent of the short-spicule group, mainly *T. daviani* and a few *O. trifurcata*. The experimental lamb was kept in a metabolism crate in a bird-proof pen which was washed daily. The resulting eggs were collected and infective larvae obtained from them. Ten thousand larvae were then given intra-uminally to another worm-free lamb and the resulting worm burden examined six weeks later. The proportion of the short-spicule group had fallen to 2.9 per cent; of these *T. daviani* was predominant.

The procedure was repeated, again using adult males of *O. circumcincta*, but this time fourth-stage larval females came from the first experimental lamb in which *O. circumcincta* constituted 97.1 per cent of the male population. The second selection further reduced the short-spicule group to 0.82 per cent of the total male population, all of which were *T. daviani*. The third and final selection produced 100 per cent *O. circumcincta* males. Throughout the experiment controls remained free from nematode infection.

Although 'cross-mating' apparently occurred between *O. circumcincta* males and females of the short-spicule group resulting in apparently normal *T. daviani* and *O. trifurcata* males together with a few aberrant and unclassifiable males (having dissimilar and unequal spicules and present only in the first selection), it would appear that a distinct fertility barrier is present, suggesting *O. circumcincta* to be a true species. This supports Trach's hypothesis⁹ that some of the more rare and unusual 'species' of the genus *Ostertagia* may be the result of interspecific variation of *O. circumcincta*, *O. trifurcata* and *T. daviani*. It is interesting to note that hybridization between two members of a closely related genus *Cooperia* has already been observed experimentally⁹.

Gametogenesis of *Plasmodium vinckei*

MANY authors in the past have observed the disappearance of gametocytes of certain blood protozoa as a result of their continuous and prolonged mechanical transmission. This phenomenon was especially studied by Vincke *et al.*¹, Rodhain *et al.*², Jadin, Yoeli and Pierreux³, and by Michiels⁴ in strains of *Plasmodium berghei* maintained in the laboratory for years by 'syringe passages'. The rodent malaria parasite *Plasmodium (Vinckei, from Garnham⁵) vinckei*⁶, isolated in 1952, behaves similarly.

It has recently been observed by Vincke, Scheepers-Biva and Bafort⁷ that *P. berghei* which has lost its ability to produce gametocytes could recover this power if kept in a state of 'quiescence'. This 'quiescence' may be obtained by transmitting the infection to adult albino rats in the meta-critical phase, where it survives in a mild, latent stage, and also by keeping the parasite at low temperatures (-75°C).

We wondered if the same phenomenon could be observed with *P. vinckei*. This parasite has been maintained since its isolation by blood transfers and has long lost its ability to produce gametocytes. We received the strain on September 14, 1962, from Algeria, through the courtesy of Prof. Fabiani. No precise information was available on the number of mechanical transmissions undergone by the strain prior to its arrival in our laboratories. Our estimation is that the strain had, at the time, passed at least 400 times, assuming that one blood transfer was carried out every ten days between the time of its discovery by Vincke in January 1952 and November 1962.

We maintained the strain by weekly transfers in mice and rats. On May 20, 1965, the strain, about thirteen years old, had been passed 68 times in 934 days in our laboratory: 59 times in mice, four times in albino rats, and in five transfers in tree rats, *Thamnomys surdaster*. Two transfers were also carried out in deep freeze at -75°C during this period.

Tables 1 and 2 summarize the details of the successive blood transfers in the two lines of animals which originated from the *P. vinckei*-infected animals received from Prof. Fabiani in September 1962.

It must be stressed that the blood of all *P. vinckei*-infected animals was regularly checked for the appearance of gametocytes and for exflagellation, but none was observed. However, after keeping *P. vinckei*-infected blood from rat 362 at low temperature (-75°C) and later passing it twice through albino rats, few gametocytes and scarce exflagellation were observed in the blood of mouse 734. More numerous exflagellation occurred in the blood of mouse 901 after the strain was maintained for a second period in deep freeze.

Table 1. SUCCESSIVE TRANSMISSIONS AFTER RECEIPT OF THE STRAIN ON NOVEMBER 14, 1962* MOUSE 901

Date	No of passage	Animal	Observations
14/11/62-20/11/62	1-2	Young mice	Weekly transfers
27/11/62-4/1/63	3-7	<i>Thamnomys</i>	Weekly transfers
2/1/63-20/9/63	8-41	Young mice	Weekly transfers
27/9/63	42	Albino rat 362	Blood in deep freeze (-75°C) tenth day after inoculation. Kept at low temperature for 67 days (8/10/63-12/12/63)
12/12/63-20/2/64	43-53	Young mice	Weekly transfers
27/2/64	54	Albino rat	Weekly transfers
13/3/64-8/5/64	55-63	Young mice	Weekly transfers
15/5/64	64	Rat reservoir	Rat clinically cured on the 30th day after inoculation and sub-inoculated on the 107th day
31/8/64	65	Rat reservoir	Rat clinically cured on the 21st day after inoculation and sub-inoculated on the 60th day
20/10/64	66	Young mouse	
30/10/64	67	Young mouse 734	Few exflagellations of microgametocytes observed in the blood on 5/11/64, the 6th day after inoculation. The blood was kept at -75°C from 6/11/64 to 13/5/65, 190 days
13/6/65	68	Young mouse 901	Exflagellation observed on 20/5/65, the 7th day after inoculation

Table 2 SUCCESSIVE TRANSMISSIONS AFTER RECEIPT OF THE STRAIN ON NOVEMBER 14, 1962 MOUSE 931

Date	No. of passage	Animal	Observations
14/11/62-20/11/62	1-2	Young mice	Weekly transmissions
27/11/62-4/1/63	3-7	<i>Thamnomys</i>	Weekly transmissions
2/1/63-20/9/63	8-41	Young mice	Weekly transmissions
27/9/63	42	Albino rat 362	Blood in deep freeze on 10th day after inoculation. Kept at low temperature for 414 days (8/10/63-26/11/64)
26/11/64	43	Young mouse	
3/12/64-11/12/64	44-45	Albino rat	Weekly transmissions
18/12/64-29/5/65	46-68	Young mice	Weekly transmissions
28/5/65	69	Young mouse	Few exflagellations observed in the blood on 3/6/65, 6 days after inoculation

We observed also exflagellation in the transfers originating from mouse 931 (Table 2). This animal was also infected with *P. vinckei* blood originating from rat 362, but the infected blood was kept for 414 days at -75°C and afterwards passed in successive transfers to mice. Exflagellation of microgametocytes in small numbers was observed at the 69th blood transfer. In the five observations in which exflagellation was hitherto observed, all were made on the sixth and seventh days after inoculation.

It may, therefore, be concluded (or at least assumed) that in *P. vinckei*, as in *P. berghei*, a period of 'quiescence' at low temperature (-75°C) favours the later re-appearance of viable gametocytes. This phenomenon, however, must be confirmed by further observations as it conflicts with investigations made in human malaria in which gametogony is present in acute cases of malaria. However, it is important that more attention should now be given to the possibility of transmission of infection by asymptomatic cases.

We thank Prof. M. Yoeli for his help in correcting our translation.

Phosphorus-deficiency Symptoms in Tobacco and Transpirational Water Loss

PHOSPHORUS-DEFICIENCY symptoms have been described for tobacco¹ and have been duplicated here in solution culture with the 'Virginia Gold' variety. The symptoms, however, do not develop until a weather condition permits a high rate of transpiration. It is under this condition that the spotting and scorching of the lower leaves of tobacco plants occur. Until there was a stress there were no visual symptoms present.

The water loss per unit of leaf area from plants to which no phosphorus was added was about twice as great for phosphorus-sufficient plants as for the phosphorus-deficient plants (Table 1). The kerosene spot test indicated that the stomata of most of the lower leaves of phosphorus-deficient plants not having any visual symptoms were closed when stomata of phosphorus-sufficient plants were fully open. Stomata on leaves on top of the plant were open in either case. The reason for this latter effect is that phosphorus in deficient plants is retranslocated to

new growth. Hence, the low water use of the phosphorus-deficient plants was related to the failure of stomata to open. When the top third of both kinds of plants was cut off, the differential transpirational water loss per unit area was about 2.5-3 times greater for the phosphorus-sufficient plants.

The classical explanation for regulation of stomatal opening is a photosynthetic decrease of carbon dioxide in the guard cell, which decreases pH. This in turn stimulates amylase which converts starch to sugar, which leads to an increase in osmotic pressure which results in opening of the stomata². More recently, the metabolism of glycolic acid has been implicated³. Oxidative phosphorylation seems to be associated in some manner, in that appropriate inhibitors prevented stomatal opening³.

Table 1. YIELDS, WATER LOSS, AND PHOSPHORUS CONTENTS OF PLANTS

Measurements	No phosphorus	0.003 M phosphorus
	Whole plants	
Dry wt. of tops (g)	24.3	70.5
Dry wt. of roots (g)	5.0	5.6
Leaf area (cm ²)	5,570	13,300
Water loss in 6 days per cm ² leaf (ml.)	0.50	0.91
Water loss in 6 days per g root (ml.)	560	2,160
P in top leaves (% dry wt.)	0.17	0.71
P in middle leaves (% dry wt.)	0.07	0.82
P in bottom leaves (spotted and scorched without P) (% dry wt.)	0.07	0.65
	Plants with tops removed	
Water loss in 6 days per cm ² leaf (ml.)	0.30	0.80
Water loss in 6 days per g root (ml.)	290	791

The role of phosphorus in metabolism is so pronounced that it is quite understandable that phosphorus deficiency can upset the functions of guard cells. The interesting point is that the reactions in guard cells are more sensitive to phosphorus deficiency than many other plant reactions in that the plants continued to grow under the conditions of the experiments. It can thus be expected that the phosphorus nutrition of at least this one plant species can regulate to a certain extent its water relations.

An intriguing question relates to the function of transpiration. In tobacco, injury occurred when transpiration could not proceed at the usual rate. This was very pronounced where the kerosene had been applied to the leaves. In phosphorus-sufficient plants the kerosene entered the stomata and there was no subsequent injury. In the phosphorus-deficient plants, the kerosene did not penetrate but formed a layer on the leaves and evidently decreased even more the exchange of gases between the leaf and atmosphere. These kerosene spots developed the usual phosphorus-deficient leaf spots for this species. The logical inference is that transpiration, or at least open stomata, serves a beneficial role. It could be that of regulating the temperature of the leaf, although the loss of a toxic volatile compound through open stomata may offer a better explanation of all the results.

The phosphorus deficiency in this plant species resulted in decreased yield of tops but in little decrease for that of roots (Table 1). This behaviour is observed for nitrogen⁴ but has not been reported for phosphorus. The volume of water transpired per gram of roots was about three times as high for the phosphorus-sufficient plants as for the phosphorus-deficient plants (Table 1).

Undernutrition and Early Embryonic Mortality in Merino Ewes

UNTIL recently there was little evidence that the plane of nutrition in early pregnancy could affect ovine foetal growth or survival¹⁻³. In the past year or so, however, it has been shown that maternal undernutrition during the first 90 days of gestation may influence foetal weight at 90 days⁴ and possibly embryo survival⁵.

In a recent investigation in this Department, short-term, severe nutritional stresses during the first 20 days of pregnancy have resulted in increased embryonic mortality. Groups of mature Merino ewes (mean body-weight, 96 lb.) were submitted to 7-day periods of sub-maintenance feeding from mating (day 0) to day 20 post-mating. Numbers of ova shed were recorded by counting corpora lutea at laparotomy, and subsequent embryonic loss or fertilization failure was assessed by return to service, pregnancy test by laparotomy about day 40, and lambing performance. The imposed stress consisted of 7 days in a bare yard, with a ration of 100 g/head/day lucerne hay, plus water. A mean body-weight loss of 3 lb. per sheep resulted.

Oestrus was synchronized, using progesterone, in 150 Merino ewes, and the ewes were hand-mated to fertile rams at the second post-synchronization oestrus. They were then divided at random on the basis of body-weight into groups of 30, 30 and 90 ewes. One group of 30 received sub-maintenance treatment from day 0 to 7 (Group 1); the second group (2), their control, grazed normally. Ewes in Groups 1 and 2 were laparotomized and their corpora lutea counted on day 12.

Laparotomy was performed on the remaining 90 ewes on day 6, and these were then randomized according to body-weight and number of ova shed into three groups of 30 ewes. Group 3 received sub-maintenance treatment from day 6 to 13 and Group 4 from day 13 to 20; Group 5 was a control. Except during sub-maintenance treatment, all ewes were paddock-grazed together on adequate pasture. During pregnancy their mean body-weight gain was 22 lb.

Following mating, the ewes were run with raddled fertile rams for 7 weeks, after which raddled infertile rams were introduced. Returns to service were recorded daily to day 60, and thereafter thrice weekly. On day 40 (± 2), ewes which had not returned to service were tested for pregnancy by laparotomy. Just prior to lambing, the groups were separated so that an accurate count of lambs born in each group was obtained.

Table 1 shows the experimental layout and the results in terms of ova shed and their eventual fate. Significantly ($P < 0.05$) less lambs were born in the treatment groups than in the controls.

Table 1. OVULATION, LAMBING AND EMBRYONIC MORTALITY DATA BY GROUPS

Group	Treatment	No. of ewes	No. of ova	No. of lambs born	Ova not represented by lambs	
					No.	Per cent
1	Day 0-7	29	44	26	18	40.9
3	Day 6-13	30	43	22	21*	48.8
4	Day 13-20	29	41	20	21	51.2
Sub total		88	128	68	60†	46.9
2	Control	30	43	31	12	27.9
5	Control	30	44	29	15	34.1
Sub total		60	87	60	27	31.0
Total		148	215	128	87	40.5

* Groups 3 and 4 versus group 5. $P < 0.10 > 0.05$

† Treatments versus controls. $P < 0.05$.

There was a high level of homogeneity within treatment groups and within controls, but differences between individual treatment and control groups did not reach significance.

Further analysis of the data showed that the loss of potential lambs was significantly higher ($P < 0.01$) among ova shed as twins than as singles.

The apparent embryonic deaths in Group 1 did not result in prolonged oestrus cycles, but in each of Groups

3 and 4, following nutritional stresses during the second and third weeks after mating, respectively, five ewes experienced cycles exceeding 22 days in length. Each of the control groups had one such ewe. This is considered to be strong supporting evidence that embryonic deaths have, in fact, resulted from the treatments.

The effect of early embryonic death on subsequent cycle-lengths is now being subjected to detailed investigation, and further work on the effect of nutritional stress in the pre-implantation period is in progress.

Human Lymphocytes cultured in Microplates

LYMPHOCYTES from peripheral blood can be stimulated to undergo blast-like transformation when cultured *in vitro*¹. This reaction is revealed by many techniques including direct morphological observations, the appearance of mitotic figures in dividing cells, and specific staining or autoradiography for the various biochemical processes involved in cell division². Although any of these techniques is satisfactory, the percentage of transforming cells in many specific immune reactions is low³, making standardization both tedious and difficult. In addition, in culture, a small percentage of lymphocytes undergo blast transformation in unstimulated controls either spontaneously or possibly because of prior sensitization of the individual to one of the products in the tissue-culture medium⁴.

We attempted to avoid some of these difficulties by using microtechniques which enabled us to test an individual's cells against a series of antigens on successive days and to have each determination matched by at least one control. So far we have only used the method of counting cells in metaphase (mitotic index) to standardize our observations. We shall report initially promising results as well as details of the method of growth of lymphocytes in microplates and some data of individual variation in responses to phytohaemagglutinin (PHA).

A disposable glass 10-ml. syringe was pre-wetted with heparin, leaving about 0.2 ml. in the syringe. Exactly 10 ml. of venous blood was drawn and the syringe was placed upright at room temperature to allow the red cells to sediment. When red cells had settled, leaving 4 ml. of plasma above the cell pack (30 min–3 h depending partially on room temperature), the needle was bent into a U-shape and by gentle pressure on the plunger the plasma was ejected into a collecting tube. This plasma contained some red cells, and the white cell counts on numerous occasions ranged from 6 million to 10 million cells per cubic ml. The cells were agitated to assure equal distribution in the plasma and one drop of the plasma-cell suspension was placed in each well of plastic disposable U-shaped microplates (Cooke Engineering Co. 220-24). Initially, we used micropipettes, but found that disposable Pasteur pipettes were sufficiently accurate for our needs. To the drop of plasma-cell suspension we added three drops of tissue culture medium, either alone as a stock solution or containing phytohaemagglutinin (PHA) or a known antigenic product. Our basic medium was Medium 199 with inactivated foetal calf serum, and penicillin, streptomycin, acromycin and mycostatin. In order to determine the optimum concentration of PHA, old tuberculin (OT), purified protein derivative (PPD) or

brucellargin, dilutions of these products were prepared and tested against several people's lymphocytes. We used a minimum concentration of PHA which produced blastogenesis in the majority of cells by the fifth day. For all other reagents we used the maximum concentration which did not produce obvious toxicity when compared to cells in control wells. All solutions were approximately 37° C at time of inoculation.

For short-term cultures, up to 6–8 days, it was not necessary to use foetal calf serum in Medium 199, the homologous plasma being sufficient to maintain growth. If we wished to culture cells in the absence of homologous serum, it was possible to centrifuge the original plasma suspension and wash and resuspend the lymphocytes in growth medium. We were not successful in growing the cells without serum in dextran-glucose as has been reported⁵. For maximum longevity of lymphocytes in culture, 40 per cent foetal calf serum in the medium plus the homologous plasma were optimal. As revealed by the colour indicator in Medium 199, this solution was quite acid. Acidity, however, did not appear to affect the cells or, possibly, had a beneficial effect. Cells did equally well in the standard incubator or in a carbon dioxide chamber at 37° C. The carbon dioxide was able to penetrate through the mineral oil seal (described below) or perhaps directly through the plastic plate, since, within several hours of being placed in the carbon dioxide chamber, the indicator in the medium assumed a more acid colour.

After the four drops of solutions were added to the wells, the latter were sealed by the addition of two drops of mineral oil. In later investigations we have found that the mineral oil could be dispensed with if plates were maintained in a moist chamber. Cells remained viable for up to 4 weeks although the numbers gradually diminished. When the experiment called for the addition of colcemid, one drop of a stock solution of colcemid was added directly to the wells the evening before the readings were to be made. The colcemid solution passed through the mineral oil without agitation within 5 or 10 min because of its relative density.

The microplates were not pre-treated or cleaned before use. The Pasteur pipettes were clean but not sterile, and the mineral oil was not autoclaved. In no instance was contamination apparent in the cultures.

All readings were made as wet mounts. Using gentle suction from a water pump, a Pasteur pipette was immersed below the fluid level of the wells and as much liquid as possible was removed without agitating the small white button of cells on the bottom. To the cells in the well, one drop of a stain consisting of 2 per cent orcein in 45 per cent glacial acetic acid was added. Cells and the stain were removed with a cotton plugged plastic disposable 1-ml. pipette. The pipette was introduced to the bottom of the well and rotated gently in order to free the cells from the plastic surface. We were surprised at the sticking properties of white cells in the U-shaped plastic wells. After several revolutions of the pipette the stain and cells were vigorously sucked up into the pipette and blown on to one pre-wiped glass slide. Immediately a cover slip (22 mm × 50 mm) was placed on the drop and this caused even spreading of the lymphocytes. Occasionally when too much mineral oil remained in the well there were mineral oil islands on the slide which interfered with the reading. Slides were sealed with nail polish and could be read for at least 8 h when desired. In general, however, they were not sealed and were studied immediately. We attempted to read two to five slides per determination, counting 200 cells and disregarding polymorphonuclear leucocytes.

When PHA was added to the cultures we had no difficulty in observing the morphological changes previously described¹. Blast-like cells were observed in cultures containing OT, PPD and brucellargin, but when these cultures were read blindly with control cultures we were unable to demonstrate differences in percentages and types

of cells which would consistently distinguish them morphologically from the controls.

In cultures to which PHA had been added, up to 7 per cent of cells were in metaphase after addition of colcemid. This percentage varied considerably among the three individuals sampled repeatedly. In one individual, ten cells in a thousand were in metaphase on day 2 (48 h after inoculation) with a peak of 78 per thousand on day 4 and still having four per thousand on day 17. This individual consistently had a few cells in metaphase even without the addition of colcemid from day 2 to day 17. A second individual had cells in metaphase only from day 4 to day 7 with a peak of 65 per thousand on day 6. On days 6 and 7, cells in metaphase were seen in cultures which did not receive colcemid. The third individual had cells in metaphase from day 5 to day 8 with a maximum of 35 per thousand on day 6. This individual had spontaneous (no colcemid added) cells in metaphase from day 5 to day 7.

Examination of cells in metaphase in the presence of OT after addition of colcemid was conducted on a tuberculin positive and tuberculin negative individual. The tuberculin negative individual did not show cells in metaphase during 25 days of observation, either in the wells with OT or in the controls. The tuberculin positive individual showed no cells in metaphase for the first 14 days. Thereafter, metaphases appeared through day 23 but never more than one per hundred cells counted. (In order to prolong the number of days of observation we only made one slide per day and occasionally we could not count more than 100 cells per slide.) On day 23, one cell in metaphase was observed in the control preparation of 160 cells counted.

The microtechnique has the advantage of providing numerous preparations from a single specimen of blood which can be tested against several antigens or against varying concentrations of reagents and under different conditions. Further, the technique permits serial sampling of a given specimen. Utilizing the mitotic index to demonstrate changes, our results were encouraging and we were able to demonstrate marked variations in responses by different individuals. We are now examining the use of various differential stains or techniques for demonstrating RNA or DNA or acid phosphatase or glycogen, all of which are reported to accumulate during different phases of blastogenesis^{2,6,7}.

A Well-preserved Grizzly Bear Skull recovered from a Late Glacial Deposit near Lake Simcoe, Ontario

THE results of a carbon-14 collagen test performed on a portion of a long bone collected in association with the skull of a grizzly-type bear of the *Ursus arctos-horribilis* complex have just been received which indicate that this remarkably well-preserved specimen died some 11,700 ± 250 years ago. The specimen was discovered in a load of gravel removed from approximately 30 ft. below the local grade of a commercial gravel pit in November 1964.

The geology of the general area has recently been investigated and mapped¹. According to the map pro-

Fig. 1

vided, this site is associated with beach sand and gravel deposits near the shore of Lake Algonquin. More recent investigations have suggested that the North Bay outlet of Lake Algonquin opened about 10,000–11,000 years ago². Further excavations and examinations of the site are planned as soon as the frost is thawed sufficiently to allow work.

Cranial measurements (mm) of this specimen (R.O.M. 34226) are as follows: condylobasal length, 322; zygomatic breadth, approximately 302; mastoid breadth, 136.6; length of palate, 164; canine-molar length of maxillary tooth row, 128; length of last three upper cheek teeth (P^4-M^2), 75.8; greatest width of palate including last molars (M^2), 87.8; width across upper canines, 70.2; height of occiput, 96.7; least interorbital breadth, 76.5; width across postorbital processes, 110.6; greatest length of mandible, 320; canine-molar length of mandibular tooth row, 145.3; length of last four lower cheek teeth (P_3-M_2), 82.8; width across lower canines, 61.7. The dentition is complete except for the incisors and the anterior or first premolars, both above and below.

There appear to be no valid records of the grizzly bear in eastern Canada (east of Manitoba) in historical times. However, there have been persistent rumours of such an animal in the Ungava region of northern Quebec, although no specimen or portion of specimen is known to exist. A large bear of grizzly size has been suspected in the interglacial deposits of the eastern Great Lakes region on the basis of post-cranial fragments, but this appears to be the first cranial specimen to be recovered from the late glacial deposits east of the Great Lakes and

provides a particularly good specimen of confirmed age.

Direct Action of Thyroxine on the Trout Pituitary *in vitro*

ALTHOUGH it is established that a negative feed-back system operates between the thyroid and pituitary in teleosts¹, the mechanism controlling the activity of the pituitary thyrotrophs has scarcely been examined. In mammals where the problem has been extensively investigated, a normal or high level of thyrotrophic activity seems to depend on stimulation from the hypothalamus and requires an intact hypothalamo-pituitary link²; a reduction of thyrotrophic activity can largely be attributed to the inhibitory action of thyroxine acting both on the hypothalamus and also directly at the pituitary level^{3,4}. In the teleost *Poecilia (Mollienesia) formosa*, experiments suggest, on the contrary, that the thyrotrophs possess an intense autonomous activity which is normally suppressed by the hypothalamus⁵. Whether or not thyroxine also has a direct inhibitory effect on their activity is not known. The present work investigates the nature of the hypothalamic influence and the effect of thyroxine on the trout pituitary, using an organ-culture technique.

Adult trout (*Salmo gairdneri*), 27–30 cm in length and weighing 200–230 g, were used for these experiments.

In experiment 4, carried out in November, the pituitaries were cut in half sagittally. One half, acting as a control, was fixed immediately in sublimated Bouin-Hollande for histological study; the other half was cultured on a hormone-free medium with an agar base, as described

Fig. 1. Uncultured pituitary; rostral basophils are darkly stained

Fig. 2. Opposite half of same pituitary as Fig. 1, cultured for 28 days on a hormone-free medium; rostral basophils are degranulated, hypertrophied and vacuolated

Fig. 3. Pituitary cultured for 8 days on a hormone-free medium; rostral basophils are degranulated

Fig. 4. Opposite half of same pituitary as Fig. 3, cultured for 8 days on a medium enriched with 20 µg/ml. thyroxine; rostral basophils are not degranulated

Arrows indicate rostral basophilic cells. All sections stained with Heilant's tetrachrome ($\times c. 95$)

Table 1

No. of pituitaries	Thyroxine concentration	Period of culture
4	40 µg/ml.	6 days
8	20 µg/ml.	8 days
2	40 µg/ml.	14 days

previously⁶. Pituitaries were cultured for 6 days (sixteen pituitaries) or 28 days (eight pituitaries) after which they were fixed, sectioned at 4µ and stained with Herlant's tetrachrome, A.F., or periodic acid-Schiff and haemalum.

In experiment B, carried out in June-July, the control half of the pituitary was cultured on a hormone-free medium while the other half was cultured on a medium to which 8.0 µg or 16.0 µg of thyroxine (Roche) was added, making a final concentration of 20.0 µg/ml. or 40.0 µg/ml. of medium. These concentrations are of the same order as those found effective *in vivo* to inhibit thyrotrophic activity in the eel⁷ or cause hypothalamic modifications in *S. gairdneri*⁸ when used as an ambient solution. Pituitaries were cultured for 6, 8, or 14 days (Table 1) and then fixed and stained as in experiment A.

Experiment A. In the control pituitary halves, rounded or angular basophilic cells with dense, homogeneous cytoplasm, staining intensely with aniline blue, periodic acid-Schiff or A.F., were always found rostrally, near the junction of the pro- or meso-adenohypophysis. These cells occurred between the other cell-types bordering the neurohypophysis and were also found scattered within the neurohypophysis itself. Similar cells were less frequently found throughout the meso-adenohypophysis, again bordering the neurohypophysis. These cells seem to correspond in position and staining reaction to those identified by Oliverneau *et al.* in *S. gairdneri* as thyrotrophs⁹. Their identification as thyrotrophs is supported by the fact that in fish with rudimentary gonads they were the only basophils present; in fish with well-developed gonads, other basophils were also present, but these were usually distinguishable from the rostral basophils by differences in position, staining intensity and size of granules.

After 6 days of culture, the staining reaction of the rostral basophils is much weaker than in the controls. The cytoplasm is less homogeneous and may be slightly vacuolated. After 4 weeks of culture, their histological appearance suggests an intense secretory activity: the cells are hypertrophied and rounded, with degranulated and very vacuolated cytoplasm; the nuclei are usually rounded with a distinct nucleolus (compare Figs. 1 and 2).

Experiment B. In ten of the twelve pituitaries cultured for 6-8 days on a thyroxine-enriched medium, the rostral basophils were less degranulated and more intensely stained than in the control half of the same pituitary, cultured on a hormone-free medium. (Compare Figs. 3 and 4.) The degree of difference between the staining reaction of the two halves was very variable: for some pituitaries the difference was very striking, in others it was much less intense; in two pituitaries, any difference between the two halves was doubtful. These variations were not correlated with the different doses of thyroxine used. In the two pituitaries cultured for 14 days, the basophils of the control cultures were completely degranulated and very vacuolated; those of the thyroxine-treated cultures were only slightly more granulated but very much less vacuolated. No consistent difference between the appearance of the nuclei in the control and thyroxine-treated halves could be observed. None of the other cell-types showed any histological changes in response to thyroxine and both the experimental and control cultures appeared very healthy, with very little or no central necrosis. It therefore seems improbable that the response of the rostral basophils is a pathological one.

In conclusion, these results indicate that the rostral basophils of the trout pituitary become hyperactive after removal from hypothalamic control; this activity can be modified by thyroxine. If the identification of these basophils as thyrotrophs is correct, then:

(a) their response to separation from the hypothalamus is comparable with the increased thyrotrophic activity observed in pituitary grafts in *Poecilia*⁵;

(b) the results would suggest that thyroxine may normally inhibit thyrotrophic activity in teleosts, as in mammals, by acting directly at the pituitary level.

MICROBIOLOGY

Differences in the Antigenic Pattern of *Azotobacter* grown on Different Nitrogen Sources

THE presence of hydrogenase in nitrogen-fixing bacteria is ascribed a specific significance, as this enzyme is considered to take part in the fixation of gaseous nitrogen¹. This assumption is based on several observations. First, a significantly higher hydrogenase activity has been demonstrated in *Azotobacter* cells assimilating molecular nitrogen instead of combined forms of nitrogen, for example, ammonium ions, nitrate or glutamic acid. Secondly, *Azotobacter* mutants which have lost their capacity for nitrogen fixation also displayed a low hydrogenase activity as compared with the wild type. Thirdly, an extract of *Clostridium pasteurianum* with a retained capability for nitrogen fixation was also shown to contain hydrogenase activity. A fraction containing the hydrogenase activity which is separated from the extract loses its ability to fix nitrogen. Recombination of the fractions restored the activity¹. The site of the hydrogenase activity in *Azotobacter* has been located to the surface components of the cell^{2,3}.

This paper comprises a study of the antigenic structure of *Azotobacter* cells grown with either nitrogen gas or ammonium ions as the sole source of nitrogen. The organism used, *Azotobacter vinelandii*, strain ATCC 7492, was cultivated in Erlenmeyer flasks on a rotary shaker at 30° C in a nitrogen-free medium⁴, or in the same medium to which ammonium chloride (1 g/l.) had been added. In the latter medium the sodium molybdate was omitted. Antigens prepared from the cells of these cultures were studied by gel precipitin tests, which were performed according to the techniques described by Feinberg⁵. The supernatants of cell suspensions, subjected to sonic treatment, were used as precipitating antigens.

Antisera were prepared in rabbits. Antigens for immunization consisted of washed suspensions of whole cells, grown in the two different media. Each type of antigen was injected into a group of three rabbits. Immunization was performed by intravenous injections of 0.5 mg of the antigen twice a week for ten weeks. The rabbits were then exsanguinated and sera collected. The globulins precipitating at half saturation with ammonium sulphate in the cold were prepared from each antiserum. The globulin precipitate was dissolved in distilled water to approximately one-tenth of the original volume of the serum.

Fig. 1. Gel-precipitin test illustrating different precipitation patterns obtained with antigens from *Azotobacter* cells grown in a medium containing ammonium ions and devoid of sodium molybdate (1) and in a nitrogen-free medium (2). Antiserum against the latter type of antigen was placed in the serum well (3)

The results are illustrated in Fig. 1. Cells grown in nitrogen-free medium displayed an antigenic pattern with five precipitation lines. Cells prepared from a culture grown in the medium containing ammonium ions developed two lines, one of which showed a reaction of identity with one of the lines of the other system. The six different antisera gave similar precipitation patterns.

The fact that the rabbits immunized with cells grown in the medium containing ammonium ions develop antibodies against all antigens detected indicates the presence of these antigens also in ammonium-grown cells. The concentration of these antigens, however, is apparently much lower in the ammonium-grown cells, since they were not detected in the gel-precipitin tests. Hydrogenase activity is regularly observed in ammonium-grown cells, although at a much lower level than in cells grown with molecular nitrogen.

As can be seen in Fig. 1, a number of additional antigens were demonstrated in the system using an extract of cells grown in a nitrogen-free medium. These antigens might possibly represent different enzymes of the nitrogen-fixing system. We hope that the technique demonstrated in this report might be of value in investigations concerned with the mechanism of nitrogen fixation.

Human Indigenous Microflora in Gnotobiotic Rats

WHILE the existence of a symbiotic relationship between man or animals and micro-organisms was recognized as early as the times of Pasteur and Metchnikoff¹, little is known concerning the evolution, complete identification, survival factors and the mechanisms which control the beneficial or pathogenic activities of the intestinal flora. Recently, however, model systems for examination of the intestinal flora have been made available in the establishment of germ-free², gnotobiotic (known flora)³ and specific pathogen-free (SPF) animals⁴.

Using the germ-free rat, we have established known microfloras composed of 1-4 predominating micro-organisms of human intestinal origin. Our work complements that of Gibbons *et al.*⁴ who established bacteria indigenous to the gingival crevice area of the mucous membranes of man in germ-free mice. Four of the organisms we used were originally isolated by Gall *et al.*^{5,6} from the billionth and higher dilutions of fresh faeces of young men participating in space investigations. These bacteria are obligate anaerobes which far outnumber the aerobes. They are only tentatively identified but have been separated into faecal anaerobe (FA) 'groups' by well-defined differences based on morphology and reaction to various media⁷. The one other pure culture used was a *Lactobacillus acidophilus* isolated from human faeces after ingestion of a commercial culture for one week. The test micro-organisms are listed in Table 1.

A semi-synthetic diet was prepared in agar-gel form by the method of Miller and Allison⁸, sealed in No. 2 cans and sterilized by irradiation to 4 Mrads in the U.S. Army Natick Laboratories cobalt-60 source. Diet composition on a dry basis in per cent is as follows: casein (22), sucrose (18), dextrose (18), dextrine (19), lard (7), corn oil (3), Wesson salt mix (4), vitamin mix (1), cellulose (4) and agar (4). One kg of the vitamin mix contained 9,750 i.u. vitamin A palmitate, 975 i.u. vitamin D₂, 2,000 mg ascorbic acid, 125 i.u. vitamin E acetate, 100 mg menadione, 60 mg thiamine hydrochloride, 30 mg riboflavin, 100 mg niacinamide, 2,000 mg choline chloride, 300 mg calcium pantothenate, 1,000 mg inositol, 50 mg pyridoxine hydrochloride, 10 mg folic acid, 1 mg biotin, 50 mg para-aminobenzoic acid, 25 mg vitamin B₁₂ and glucose diluent to make up the balance of the kilogram. Agar was dissolved in hot water before being added to a dry mix of the other dietary components. Ratio of dry ingredients to added water was 1:1.

After sterilization, the above diet was fed to weanling germ-free rats of the Charles River Breeding Laboratories strain maintained in Trexler-type⁹ flexible film isolators. At the start of the experiments, animals were inoculated with desired micro-organisms which were brought into the isolators in sealed ampoules and then introduced into the diet which had been withheld from the rats for 12 h. The experiment consisted of two runs conducted two months apart with experimental groups as shown in Table 1. Germ-free rats and gnotobiotics inoculated with normal rat caecum contents served as controls. There were five rats per group. Each experiment was of three weeks duration.

Establishment of inoculated organisms was determined by culturing of fresh faecal samples obtained in the isolators and of the contents of the gastrointestinal tract at the termination of the runs. Samples were cultured aerobically and anaerobically in thioglycollate broth and Gall's medium⁷. In addition, Gram stain smears were examined microscopically.

At the end of the first run, cultures taken from the jejunum, caecum, and colon showed that the mono-contaminants FA 1, 9, 13 and 15 were established in greatest concentration in the colons and caeca. Very few micro-organisms were found in the jejunum as compared with the caecum and colon. Therefore, when the second run was terminated, only the caeca were sampled for bacteriological culturing. As shown in Table 1 (run No. 2), mono-inoculated FA 13 was found to be associated with a contaminant which was not intentionally introduced. Also, in the tetra-inoculated group FA 13 and FA 15 were identified as being present, but morphological similarities made it difficult to determine definitely whether both FA 1 and FA 9 were established. While there was no quantitation, it was noted that FA 15 predominated in the tetracontaminated rats.

Early growth as measured by weight gain was the overall measure of physiological response to the artificially

Table 1. WEIGHT GAIN, CAECUM SIZE AND CHOLESTEROL-LEVELS OF GNOTOBIOTIC RATS MAINTAINED GERM-FREE OR INOCULATED WITH ORAL DOSES OF HUMAN AND RAT ORIGIN MICRO-ORGANISMS. ALL ANIMALS WERE FED THE SAME STERILE SEMI-SYNTHETIC DIET FOR THREE WEEKS

Micro-organisms introduced *	Three-week body-weight gain (g)†	Caecum as % of body weight	Plasma cholesterol‡ (mg/100 ml.)	Liver cholesterol‡ (mg/g)
Run No. 1				
Germ-free	74 ± 3 (c)§	7.1 (a)	95 ± 5 (a)	2.52 ± 0.11 (ab)
FA 1 (<i>Sphaerophorus</i> or <i>Catenabacter</i>)	95 ± 5 (a)	6.8 (ab)	97 ± 10 (a)	2.78 ± 0.28 (ab)
FA 9 (<i>Bacteroides</i>)	80 ± 5 (bc)	6.2 (ab)	124 ± 5 (b)	3.23 ± 0.16 (b)
FA 13 (<i>Yelloneilla</i> sp.)	98 ± 2 (a)	5.6 (ab)	99 ± 5 (a)	2.16 ± 0.10 (a)
FA 15 (<i>Fusiformis</i> sp.)	91 ± 2 (ab)	5.1 (b)	158 ± 3 (b)	2.64 ± 0.18 (ab)
Run No. 2				
Germ-free	83 ± 6 (a)	7.1 (a)	88 ± 3 (b)	2.41 ± 0.19 (a)
Rat caecum organisms	101 ± 6 (b)	2.4 (c)	78 ± 15 (a)	2.21 ± 0.17 (a)
FA 1, 9, 13, 15	83 ± 4 (a)	6.6 (ab)	95 ± 5 (b)	2.54 ± 0.08 (a)
FA 13 + <i>Lactobacillus acidophilus</i>	77 ± 3 (a)	6.1 (b)	73 ± 3 (a)	2.11 ± 0.13 (a)
FA 13 + contaminant	87 ± 2 (ab)	7.3 (a)	71 ± 15 (a)	2.14 ± 0.20 (a)
<i>Lactobacillus acidophilus</i>	90 ± 3 (ab)	7.3 (a)	74 ± 15 (a)	2.17 ± 0.06 (a)

* FA (faecal anaerobic) micro-organisms only tentatively identified.

† Average body-weight gains and standard errors, not corrected for caecum weights.

‡ Cholesterol determined by the fluorometric procedure of R. W. Albers and O. H. Lowry (*Anal. Chem.*, 27, 1329; 1955).

§ Common letters denote statistically similar group values by analysis of variance.

established microfloras. As shown in Table 1, mono-established organisms varied in their weight-gain promoting ability. The weight gains of monocontaminated rats were 8–32 per cent greater than those obtained in the flora-free animals. In run No. 2 the greatest weight gain was obtained in the group polycontaminated with normal rat caecum organisms. Since the average gain of 4.8 g/day compares favourably with that of conventional rats, it may be assumed that the sterile diet used was of high nutritional value. Animals with the other induced microfloras in run No. 2 were not statistically different in body weight from germ-free controls. The failure of micro-organisms which increased weight gain as monocontaminants to do so when associated together indicates that physiological response is governed not only by the type of micro-organisms present but also by the outcome of complex competitive inter-relationships.

Enlarged caeca, characteristic of the germ-free state in rodents², were found in all rats except those polycontaminated with rat caecum organisms. Omitting this group, the caeca which varied from 5.1 to 7.3 per cent of body weight were not as large as those obtained by some workers. This may be a diet-influenced effect. Nevertheless, the presence of enlarged caeca indicates that none of the human-origin micro-organisms established in the germ-free rat, either singly or in combination, were physiologically adequate.

Plasma and liver total cholesterol-levels were also influenced by the introduced micro-organisms. In this respect, our results are not in agreement with those of Graber *et al.*¹⁰ who found that differences in plasma cholesterol of conventionally maintained rats were the result of dietary factors rather than of alteration in bacterial flora. Average plasma cholesterol of rats monocontaminated with FA 15 organisms was significantly higher than that of the germ-free rats and two other monocontaminated groups. Also, liver cholesterol-levels in FA 9 rats were statistically greater than those of FA 13 animals.

The reported pattern of higher cholesterol-levels in germ-free rats over conventional rats¹¹, probably due to a decrease in cholesterol catabolism in the germ-free rats¹², was observed in run No. 2. However, there was one exception in that the tetracontaminated group had the highest plasma cholesterol levels. An explanation for the cholesterol elevation may be that FA 15, which predominated in the tetracontamination, by itself results in a high level of blood cholesterol. Thus, our results appear to indicate that, while some intestinal micro-organisms may help to eliminate cholesterol, others may contribute directly or indirectly to the body cholesterol pool.

While we have established human indigenous micro-organisms in germ-free rats, we emphasize that differences exist between the two species. Two important differences are that the rat has a caecum and practices coprophagy. Our results demonstrate that the germ-free rat can

maintain specific organisms native to other species, with subsequent physiological changes.

PSYCHOLOGY

Neural Volleying: Upper Frequency Limits detectable in the Auditory System

THE discovery that nerve fibres exhibit a refractory period which limits the number of impulses produced in a given time dealt a death blow to early 'telephone' theories, which postulated that information concerning the frequency of a tone (or a Fourier component of a complex sound) was faithfully reproduced by the rate of discharge of an individual fibre. Simple 'telephone' theories of neural encoding of pitch were replaced by 'volley' theories¹ in which stimulus frequency was encoded in the auditory nerve as a whole. According to 'volley' theory, different fibres firing at sub-multiples of the stimulating frequency produce a composite discharge that faithfully reproduces the frequency of the stimulating wave-form.

Evidence for 'volleying' in the auditory system comes primarily from electrophysiological experimentation. Wave activity of the eighth nerve (presumed an envelope of a large number of individual fibre discharges) was observed by Derbyshire and Davis² to be synchronous with the stimulus tone up to a limiting frequency of about 4 kc/s. More recent studies³ utilizing computer averaging

of eighth nerve activity failed to demonstrate synchronous activity beyond 3 kc/s. A report⁴ on wave activity in the trapezoid body indicated an upper frequency limit of synchronous activity about 2.5 kc/s.

In the present experiment the upper limits of volleying were investigated by recording the wave activity generated in the superior olivary complex (SOC) in anaesthetized cats⁵. Five chronically implanted animals and five acute preparations were used. The animals were placed in a head-holder equipped with hollow ear bars into which were introduced tone bursts, 15–20 msec in duration with a 1-msec rise time and a fixed phase of onset. Stimulation was to the ear contralateral to the SOC because the amplitude of the wave response was larger and the possibility of picking-up volume-conducted cochlear microphonics, eighth nerve potentials or possible cochlear nuclei potentials was minimized.

Recording was monopolar with respect to an indifferent electrode on the bone over the frontal sinus or to a flap of skin. Insulated insect pins were used and the recording site histologically verified. The SOC potentials were amplified, passed through a band-pass filter⁶, and then either fed directly into a computer of average transients or recorded on magnetic tape for averaging when replayed at a slower speed⁷. The computer-averaged wave-forms were written out with an x-y recorder.

Earlier observations of SOC potentials in which a computer was not employed had usually failed to detect synchronous wave activity above 3 kc/s⁴. With response-averaging, no difficulty was encountered in demonstrating synchronous activity well beyond 3 kc/s, although amplitude declined markedly with higher stimulus frequencies. As the frequency of the stimulating tone increased above 3 kc/s, more and more intense tones were required to raise the signal above the noise-level.

Averaged responses to stimulus tones of different frequency are presented in Fig. 1. In this figure it is readily apparent that the frequency of the stimulating tone is reliably reproduced in the SOC wave up to 4.3 kc/s. The upper limits for demonstrating synchronous activity varied from animal to animal and this was probably a result of differing electrode positions. In all cases it was above 3.5 kc/s. A definite upper limit could not be established. Other than electrode position, the criterion for determining whether the averaged potentials were generated in the SOC was that the latency of the response to a high-intensity tone was greater than 2 msec. About 4 kc/s the amplitudes of the SOC potentials were so small that the limits of resolution of the recording system were approached, and it became difficult to separate SOC potentials from possible artefacts. These artefacts included volume conducted potentials from other areas, 'broadcasting' from the earphone and possible mechanical vibration of the head-holder with high intensity tones.

That computer-averaged SOC responses show an upper frequency limit higher than any demonstrated in the eighth nerve is possibly due to differences in experimental conditions and the large amplitude of the potentials generated in the SOC. The surprising fact is that the introduction of a synapse at the cochlear nuclei and probably another at the accessory nucleus (the method of recording cannot distinguish presynaptic from postsynaptic potentials) apparently does nothing to disturb the temporal relationship of inter-fibre volleying. This fact implies extremely accurate temporal resolution at the cochlear nuclei relay to maintain stable inter-fibre volleying relationships. Temporal variability of inter-fibre discharge can also be introduced by minute variation in the length or diameter of the trapezoid body fibres innervating the accessory nucleus, but this variability is either minimal or somehow counterbalanced.

There is evidence from single-unit investigations that extensive re-coding of auditory information often occurs in the cochlear nuclei⁸. It is evident from the present study, however, that the temporal information encoded in the

Fig. 1. Computer-averaged responses recorded from the superior olivary complex of an anaesthetized cat. Stimuli were tone bursts of different frequency delivered to the ear contralateral to the SOC. The number of responses averaged is *N*. Stimulus intensity expressed in decibels above 0.0002 dynes/cm². Vertical calibration line is 0.1 mV

eighth nerve by means of inter-fibre volleying is encoded in the same way by the trapezoid fibres innervating the SOC. That the detectable upper frequency limits of the wave activity recorded from the eighth nerve and SOC are about equal implies little or no loss of the temporal information encoded by inter-fibre volleying. Apparently, the accessory nucleus of the SOC, which is evidently primarily involved in binaural localization⁹, finds it convenient to receive temporal information in a form relatively unmodified from that found in the eighth nerve.

FORTHCOMING EVENTS

Monday, December 20

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. D. G. Drummond: "Recent Developments in the Control of Commensal Rodents".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER (with a good honours degree in botany and/or zoology and a special interest in cell biology and microbiology) in BIOLOGY—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (December 31).

ASSISTANT LECTURER (with special qualifications in experimental physics, aeronomy or astronomy) in APPLIED MATHEMATICS (GEOPHYSICS)—The Secretary, The Queen's University, Belfast, Northern Ireland (December 31).

CHAIR IN AND HEADSHIP OF THE DEPARTMENT OF METALLURGY AND MATERIALS TECHNOLOGY—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (December 31).

LECTURER IN EDUCATION COMBINED WITH GEOGRAPHY—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (December 31).

LECTURER IN EDUCATION with special reference to the teaching of science or engineering or mathematics in Technical Colleges and Sixth Forms—The Registrar (Room 39, O.R.B.), The University, Reading (December 31).

LECTURER OR ASSISTANT LECTURER IN MATHEMATICAL SCIENCES—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (December 31).

LECTURER (preferably with an interest in physical chemistry) in CHEMISTRY at the University of the West Indies—The Inter-University Council, 33 Bedford Place, London, W.C.1 (December 31).

LECTURER (with an Hons. B.Sc. degree in biochemistry or equivalent qualification, and preferably a dental qualification) in DENTAL BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (December 31).

LECTURERS OR ASSISTANT LECTURERS (with interest in inorganic chemistry, physical chemistry, or theoretical chemistry) in CHEMISTRY—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 88C (December 31).

RESEARCH STUDENT IN THE DEPARTMENT OF PHYSICS to carry out research with a small group working on certain aspects of vacuum breakdown within the Research School of Ionization Physics—The Registrar, University College of Swansea, Singleton Park, Swansea (December 31).

SENIOR RESEARCH FELLOW IN THE DEPARTMENT OF METALLURGY to carry out research in the technology of primary metal production either by the conventional or powder routes—The Registrar, University College of Swansea, Singleton Park, Swansea (December 31).

ASSISTANT EDITORS AND EDITORIAL ASSISTANTS (preferably with a good honours degree in chemistry and some postgraduate experience) for various duties with the Society's scientific publications—The General Secretary, The Chemical Society, Burlington House, Piccadilly, London, W.1 (January 1).

ASSISTANT LECTURER IN STATISTICS IN THE DEPARTMENT OF APPLIED STATISTICS (formerly the Unit of Biometry), for duties which will involve teaching, consulting and research—The Registrar (Room 39, O.R.B.), The University, Reading (January 1).

HEAD (with high academic qualifications and considerable research experience in genetics and plant breeding, not necessarily with vegetables) OF THE PLANT BREEDING SECTION—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (January 3).

SENIOR LECTURER IN CLINICAL MEDICINE; a LECTURER IN PATHOLOGY, and a LECTURER IN SURGERY at the University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (January 7).

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (with first- or second-class honours degree in chemistry or microchemistry with suitable postgraduate experience; or an honours degree in agricultural chemistry with postgraduate experience) in THE CHEMICAL RESEARCH DIVISION, MINISTRY OF AGRICULTURE, to undertake research work in animal nutrition (successful candidate may be required to undertake teaching duties in the Faculty of Agriculture in Queen's University, Belfast)—The Secretary, Civil Service Commission, Stormont, Belfast, 4, Northern Ireland (January 7).

LECTURER IN ANCIENT PHILOSOPHY—The Secretary of Faculties, University Registry, Oxford (January 8).

SENIOR LECTURER/LECTURER IN PHARMACOLOGY IN THE DEPARTMENT OF MATERIA MEDICA AND THERAPEUTICS—The Secretary, The University, Aberdeen (January 8).

SENIOR LECTURER IN VETERINARY MEDICINE at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, January 14).

CHAIR OF PHYSICAL CHEMISTRY—The Secretary, The Queen's University, Belfast, Northern Ireland (January 15).

CHAIR OF PSYCHOLOGY at the University of Cape Town—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (January 15).

PROFESSOR OF GEOBOTANY—The President of the Board of the Swiss Federal Institute of Technology, Leonhardstrasse 33, CH-8006, Zurich, Switzerland (January 15).

SENIOR LECTURER OR LECTURER (with a higher degree in psychology and preferably with specialization in personality and social psychology) in PSYCHOLOGY at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 17).

ASSISTANT LECTURERS OR LECTURERS (2) (preferably with interests in either theoretical chemistry, chemical crystallography or physical organic chemistry, and research experience at post-doctoral level) in THE DEPARTMENT OF CHEMISTRY—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (January 22).

FELLOW/LECTURER IN ANTHROPOLOGY within the Centre for Middle Eastern and Islamic Studies—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 28).

ASSISTANT OR ASSOCIATE PROFESSORS (with research experience in biochemistry, plant physiology or experimental biology) in BIOCHEMISTRY AND BIOLOGY—Head of the Bioscience Department, Brock University, St Catharines, Ontario, Canada (January 31).

LECTURER OR SENIOR LECTURER (suitably qualified graduate in science, medicine or veterinary science, and preferably with some research experience) in PHYSIOLOGY at Massey University of Manawatu, Palmerston North, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall London, S.W.1 (New Zealand and London, January 31).

LECTURER/SENIOR LECTURER (with a suitable, preferably a higher degree in science or agricultural science and experience in the field of plant physiology) in AGRONOMY (Plant Physiology) in THE FACULTY OF AGRICULTURE AND HORTICULTURE, Massey University of Manawatu—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 31).

OFFICIAL FELLOW IN ENGINEERING SCIENCE—The Principal, Brasenose College, Oxford (January 31).

SCIENTIFIC OFFICER OR SENIOR SCIENTIFIC OFFICER (botanist with a good honours degree) to study the physiology of sucrose storage in sugar beet—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (January 31).

SENIOR LECTURER IN METEOROLOGY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 31).

SENIOR LECTURER IN STATISTICAL MATHEMATICS and/or NUMERICAL MATHEMATICS at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 31).

LECTURER (preferably graduate in sociology and social anthropology) in SOCIOLOGY OF THE MIDDLE EAST in THE DEPARTMENT OF SOCIAL THEORY AND INSTITUTIONS—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (February 1).

LECTURER (with a good honours degree in metallurgy or physics and preferably post-doctoral experience in the application of X-ray diffraction methods to the study of metals) in METALLURGY—The Registrar, The University, Sheffield (February 15).

CHAIR OF BIOCHEMISTRY—The Registrar, University of Strathclyde, Glasgow, C.1 (February 28).

ANDRÉ DOREMAN FELLOW FOR RESEARCH IN MINING ENGINEERING and/or MINING TECHNOLOGY—The Registrar, Imperial College of Science and Technology, London, S.W.7 (March 31).

LECTURER (with a degree in pure science or agricultural science) in ENTOMOLOGY in THE DEPARTMENT OF AGRICULTURAL ZOOLOGY, Lincoln College (University of Canterbury), New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, March 31).

ASSISTANT DIRECTOR (with a degree in agriculture, agricultural botany or pure science, a reading knowledge of two or more modern languages, the ability to write good concise English, and preferably some editorial experience) OF THE COMMONWEALTH BUREAU OF PASTURES AND FIELD CROPS, Hurley, near Maidenhead, Berks—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, near Slough, Bucks.

GRADUATE ASSISTANT (science or biology graduate) in THE CYTOLOGY DEPARTMENT of a large modern group laboratory, for duties which will include routine cytodiagnostic and research work under the guidance of the Consultant Pathologist in charge—The Director or Consultant in charge of the Cytodiagnostic Unit, Group Laboratory, St. Stephen's Hospital, Fulham Road, Chelsea, London, S.W.10.

LECTURER IN INORGANIC CHEMISTRY in THE DEPARTMENT OF CHEMICAL TECHNOLOGY—The Registrar, Bradford Institute of Technology, Bradford, 7.

LECTURER OR ASSISTANT LECTURER in GEOGRAPHY—The Registrar, The University, Hull.

LECTURER (with qualifications in communication and control theory, operational research or stochastic processes) in MATHEMATICS—The Registrar (Room 39, O.R.B.), The University, Reading.

RESEARCH ASSISTANT to work on radio-biological and oncological problems using histological, histochemical, autoradiographic and electron-microscope techniques—The Deputy-Director, Strangeways Research Laboratory, Worts Causeway, Cambridge.

RESEARCH ASSISTANT (with a good honours degree in physics or a good general honours degree including physics) in PHYSICS for research in the field of either radiation physics or vacuum physics, and would lead to the higher degree of either M.Sc. or Ph.D.—Head of the Department of Physics, The Polytechnic, Regent Street, London, W.1.

RESEARCH ASSISTANT (with H.N.C. in physics or chemistry, or an equivalent qualification) to join a small group working on high temperature chemistry and physics—Dr. A. J. Croft, Clarendon Laboratory, University of Oxford, Oxford.

RESEARCH FELLOW (young research worker, either post-Ph.D., or about to submit a Ph.D. dissertation) in THEORETICAL PHYSICS in one of the following fields: elementary particle physics, nuclear physics or solid state physics—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Stanmer, Brighton, Sussex.

RESEARCH LABORATORY TECHNICIAN to assist in a study of the physiology and biochemistry of isolated mammalian nerve cells—The Chief Laboratory Technician, Battersea College of Technology Annex, 14 Falcon Road, London, S.W.11.

SCIENTIFIC INFORMATION OFFICER (with a degree in agriculture or related subject and a flair for languages, including English) to join a team engaged in publishing the latest research findings on temperate and tropical grasslands and annual field crops in two journals of international repute—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, nr. Maidenhead, Berks.

SENIOR LABORATORY TECHNICIAN (preferably with some experience in metallurgical analysis) to supervise the chemical laboratories of the Department of Metallurgy, Sir John Cass College, Whitechapel High Street, London, E.1—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

SENIOR PHYSICIST to take charge of the Physics Department, Radiotherapy Centre, St. William's Hospital, Rochester, Kent—The Group Secretary, Medway and Gravesend Hospital Management Committee, Medway Hospital, Gillingham, Kent.

SENIOR TECHNICIAN (CHEMICAL PATHOLOGY) for research projects, mainly enzymological—Dr. D. M. Matthews, Deputy Director, Vincent Square Laboratories of Westminster Hospital, 124 Vauxhall Bridge Road, London, S.W.1.

SENIOR TECHNICIAN (preferably with experience of working with an electron microscope and/or electronics) in THE CRYSTALLOGRAPHY RESEARCH DEPARTMENT—The Administrative Assistant, Birkbeck College (University of London), Malet Street, London, W.C.1, quoting Ref. C.S.T.

TECHNICIAN (with a good G.C.E. in science subjects including chemistry, and preferably previous experience in biochemical techniques) FOR A RESEARCH UNIT—The Administrator, Department of Biochemistry, The University, South Parks Road, Oxford.

TECHNICIAN (with previous experience of chromosome work) to work in the Chromosome Laboratory of the Department of Clinical Research at the Royal Marsden Hospital, Fulham Road, London, S.W.3—The Secretary, Institute of Cancer Research, 34 Sumner Place, London, S.W.7, quoting Ref. 301/B/229.

- Ditch or Crash-Land? By B. W. Townshend. Pp. vii+60. (Farnham, Surrey: B. W. Townshend, Little Gables, Crooksbury Road, 1965.) [311]
- Tavistock Pamphlet No. 12: Towards a Theory and Practice of Social Architecture: The Building of Indispensable Institutions. By Dr. Howard V. Perlmutter. Pp. vii+60. (London: Tavistock Publications, 1965.) 12s. 6d. net. [311]
- Manchester Literary and Philosophical Society. Memoirs and Proceedings. Vol. 107, 1964-65. Pp. 142+hi. (Manchester: Manchester Literary and Philosophical Society, 1965.) 31s. 6d. [311]
- The British Cast Iron Research Association. Forty-fourth Annual Report for the year ending 30th June 1965. Pp. 111. (Alvechurch, Birmingham: The British Cast Iron Research Association, 1965.) [311]
- The West of Scotland Agricultural Colleges. Research Bulletin No. 84: Comparison of Production of Four Varieties of White Clover. By I. V. Hunt, R. D. Harkess and T. W. Martin. Pp. 39. (Auchincruive, by Ayr: The West of Scotland Agricultural College, 1965.) 1s. [311]
- University of Oxford. Annual Report of the Curators of the Bodleian Library for 1963-64. Pp. 28. (Supplement No. 9 to the *University Gazette*, August, 1965.) (Oxford: The University, 1965.) 2s. 6d. [311]
- Medical Research Council Monitoring Report Series, No. 11: Assay of Strontium-90 in Human Bone in the United Kingdom, Results for 1964, Part 2. Pp. v+17. (London: H.M. Stationery Office, 1965.) 1s. 9d. net. [311]
- Queen Elizabeth College (University of London). The Development of Experimental Botany. By Prof. J. Sidelman. (Inaugural Lecture delivered 19th January, 1965.) Pp. 17. (London: Queen Elizabeth College, 1965.) [311]
- Marine Biological Station, University of Liverpool. Annual Report No. 77 for 1964. Pp. 55. (Liverpool: Liverpool University Press, 1965.) [311]
- The Overseas Development Institute, Ltd. The Decade of Development—a Study in Frustration? (A lecture delivered in London under the auspices of the Overseas Development Institute on May 3, 1965.) Pp. 23. (London: The Overseas Development Institute, 1965.) 3s. 6d. [311]
- Scottish Society for Research in Plant Breeding: Scottish Plant Breeding Station. Record 1965. Pp. 236. (Pentlandsfield, Roslin, Midlothian: Scottish Society for Research in Plant Breeding, 1965.) [311]
- Publications List of the Commonwealth Agricultural Bureaux 1965-66. Agriculture; Animal Health; Forestry. Pp. 42. (Farnham Royal: Commonwealth Agricultural Bureaux, 1965.) [311]
- The Institute of Personnel Management, 1964-1965. Pp. 41. (London: The Institute of Personnel Management, 1965.) [311]
- Proceedings of the Society for Psychical Research, Vol. 54, Part 197 (August, 1965): The Blue Vase. By G. W. Lambert. Time and ESP. By H. A. C. Dobbs. Pp. 233-361. (London: The Society for Psychical Research, 1965.) 12s. 6d.; 2 dollars. [311]
- Ministry of Technology. Research for Industry 1964. (A Report on work done by industrial research associations in the Government scheme.) Pp. iii+72+20 plates. (London: H.M. Stationery Office, 1965.) 8s. net. [311]
- Friends of the Lake District. Report and News Letter, September 1965. Pp. 18. (Ulverston: Friends of the Lake District, 1965.) [311]
- Procter and Gamble, Ltd. Financial Statement for the year ended 30th June 1965. Pp. 16. (Newcastle upon Tyne: Procter and Gamble, Ltd., 1965.) [311]
- National Union of Teachers. What Chance Has Your Child? By Kathleen Gibberd. (A Study of the Effects of Overcrowded Classes in Our Schools.) Pp. 15. (London: National Union of Teachers, 1965.) 6d. [311]

Other Countries

- Republic of South Africa: Department of Commerce and Industries. Division of Sea Fisheries. Investigational Report No. 52: Ocean Currents and Water Masses at 1,000, 1,500 and 3,000 Metres in the South-West Indian Ocean. By G. A. Visser and M. M. Van Niekerk. Pp. 40. Investigational Report No. 53: The Rock Lobster of the South African West Coast, *Jasus lalandii* (H. Milne-Edwards). 1: Notes on the Reproduction Biology and the Determination of Minimum Size Limits for Commercial Catches. By A. E. F. Heydorn. Pp. 32. (Sea Point, Cape Town: Division of Sea Fisheries, 1965.) [411]
- Bilan des Maladies et Infirmités Découlées dans les Classes de Milice 1953-1960 en Belgique. Par F. Twisselmann, J. François, P. Moureau et S. Vrydagh. (Extrait de *Population et Famille*, No. 5.) Pp. 81. (Brussels: National Center for Radiobiology and Genetics, 1965.) [411]
- New Zealand. Report of the Board of Trustees of the National Art Gallery and Dominion Museum for the year ended 31 March 1965. Pp. 28. (H. 21.) (Wellington: Government Printer, 1965.) 1s. 6d. [411]
- Salamandra*, Band 1, Heft 1/2 (September 1965). Herausgegeben von der Deutschen Gesellschaft für Herpetologie und Terrarienkunde. Pp. 52. (Frankfurt/Main-Niederrad: Deutsche Gesellschaft für Herpetologie und Terrarienkunde, 1965.) [411]
- Annals of the New York Academy of Sciences. Vol. 105, Article 18: *In Vivo* and *In Vitro* Behavior of Clotting Factors in Blood and Tissues. By F. Nour-Eldin. Pp. 983-1004. 2 dollars. Vol. 118, Article 13: Further Approximations to the Blastus Function. By Ernest D. Kennedy. Pp. 575-584. 1.50 dollars. Vol. 118, Article 14: Application of Electrodynetic Phenomena in Civil Engineering and Petroleum Engineering. By S. A. Anbar, O. M. Beeson and G. V. Chillingar. Pp. 585-602. Vol. 118, Article 15: Mercenene: *In Vivo* Effects of Mollusk Extracts on the Sarcoma 180. By M. Rosarli Schneer and Cecilia V. Huala. Pp. 603-610. 1.50 dollars. Vol. 118, Article 23: The Formation of Noble Gas Compounds. By Leland G. Allen. Pp. 883-898. 1.50 dollars. (New York: New York Academy of Sciences, 1964 and 1965.) [411]
- The Research Institute of Applied Electricity, Hokkaido University Monograph Series. No. 11: Network Synthesis with Multiwire Lines. By Prof. A. Matsumoto. Pp. 98. No. 12: Developments in Multiwire Networks. By Prof. A. Matsumoto. Pp. 107. No. 13: Dipole, Molecule and Chemistry. By Prof. K. Higasi. Pp. 67. (Sapporo, Japan: The Research Institute of Applied Electricity, Hokkaido University, 1963, 1964 and 1965.) [411]
- Regeneratie, Volumetrische en Numerieke Hypertrofie van Skeletspieren bij Kikker en Rat. Door Walter Reitsma. Pp. 118. (Amsterdam: Vrije Universiteit, 1965.) [411]

- Institut for Atomenergi, Kjeller Research Establishment. Kjeller Report No. 96: Correlation Between Calculated and Measured Mechanical Properties of Thin-Walled Fuel Element Canning Tubes of Stainless Steel. By Erik Brodahl and Steinar Aas. Pp. 14+13 figures. (Kjeller, Norway: Institut for Atomenergi, Kjeller Research Establishment, 1965.) [411]
- Food and Agriculture Organization of the United Nations. Indo-Pacific Fisheries Council. Proceedings—11th Session, Kuala Lumpur, Malaysia, 16-21 October, 1964, Section 1. Pp. iii+90. (Bangkok: IPFC Secretariat, FAO Regional Office for Asia and the Far East, 1965.) [411]
- Indonesia: Ministry of Air Communications. Meteorological and Geophysical Service. Earthquakes in Indonesia 1962. Pp. 13. (Jakarta: Ministry of Air Communications, Meteorological and Geophysical Service, 1966.) [411]
- Transactions of the American Philosophical Society. New Series, Vol. 55, Part 6: The Pyramid of the Sun at Teotihuacán: 1959 Investigations. By René Millon, Bruce Drewitt and James A. Benneyhoff. Pp. 93. (Philadelphia: The American Philosophical Society, 1965.) 3 dollars. [411]
- Publications of the Dominion Observatory, Ottawa. Vol. 30, No. 3: Bibliography of Seismology, Items 17127-17944 (September-December, 1963). By F. E. Langill and J. H. Hodgson. Pp. 75-117. (Ottawa: Queen's Printer, 1965.) 1 dollar. [411]
- United States Department of the Interior. Geological Survey. Water-Supply Paper 1475-Q: Present and Future Water Supply for Mammoth Cave National Park, Kentucky. By R. V. Cushman, R. A. Krieger and John A. McCabe. Pp. v+601-647. 25 cents. Water-Supply Paper 1662-B: Specific Yield—Laboratory Experiments Showing the Effect of Time on Column Drainage. By R. C. Prill, A. I. Johnson and D. A. Morris. Pp. iv+55. 25 cents. Water-Supply Paper 1682: Magnitude and Frequency of Floods in the United States. Part 8. Western Gulf of Mexico Basins. By James L. Patterson. Pp. xvi+506+plate 1. Water-Supply Paper 1787: Ground-Water Conditions and Storage in the Central Sevier Valley, Utah. By Richard A. Young and Carl H. Carpenter. Pp. vi+95+plates 1-6. Water-Supply Paper 1792: Ground Water in Permafrost Regions—An Annotated Bibliography. By John R. Williams. Pp. iii+294+plate 1. 1.25 dollars. Water-Supply Paper 1794: Ground Water Resources of Pavant Valley, Utah. By R. W. Mower. Pp. v+73+plates 1-10. Water-Supply Paper 1802: Fluvial Sediment of the Mississippi River at St. Louis, Missouri. By Paul R. Jordan. Pp. vii+89. (Washington, D.C.: Government Printing Office, 1965.) [411]
- United States Department of the Interior. Geological Survey. Water-Supply Paper 1804: Drought of the 1950's, with Special Reference to the Midcontinent. By R. L. Nace and B. J. Plunowski. Pp. v+38+plates 1 and 2. Water-Supply Paper 1809-D: An Evaluation of Aquifer and Well Characteristics of Municipal Well Fields in Los Alamos and Gaje Canyons, Near Los Alamos, New Mexico. By R. L. Cushman. Pp. v+50+plates 1-4. 1 dollar. Water-Supply Paper 1809-L: Ground Water Pumpage and Water-Level Changes in the Milwaukee-Waukesha Area, Wisconsin, 1950-61. By J. H. Green and R. D. Hutchinson. Pp. iii+19+2 plates. Water-Supply Paper 1809-J: Water-Resources Reconnaissance of the Ouachita Mountains, Arkansas. By Donald R. Albin. Pp. iii+14+plate 1. 45 cents. Water-Supply Paper 1809-M: Elimination of Thermal Stratification in Reservoirs and the Resulting Benefits, with special emphasis on Study of Lake Whittford, California. By Gordon E. Koberg and Maurice B. Ford, Jr. Pp. iv+28. 15 cents. Water-Supply Paper 1809-N: Effects of Waste Water from A.E.C. Plant on the Hydrology of Glowegee Creek at West Milton, New York, 1958-61. By F. H. Pauszek and F. H. Ruggles. Pp. iv+29. 20 cents. (Washington, D.C.: Government Printing Office, 1965.) [411]
- Annals of the New York Academy of Sciences. Vol. 127, Article 1. Comparative Cardiology. By A. M. Albina and 80 other authors. Pp. 1-876. (New York: New York Academy of Sciences, 1965.) [511]
- Smithsonian Miscellaneous Collections. Vol. 148, No. 8: Middle and Late Turonian Oysters of the Lophia lugubris Group. By Erle G. Kaufmann. (Publication No. 4602.) Pp. i+92+8 plates. (Washington, D.C.: Smithsonian Institution, 1965.) [511]
- Canada: Department of Mines and Technical Surveys. Geological Survey of Canada. Bulletin 115: Chemical Analyses of Canadian Rocks, Minerals, and Ores, Compiled from the Records of the Geological Survey of Canada for the period 1846-1965. By J. A. Maxwell, K. R. Dawson, Margaret E. Tomlinson, Dorothy M. E. Pocock and Diane Tetreault. Pp. 476. (Ottawa: Queen's Printer, 1965.) 6.50 dollars. [511]
- Records of the Australian Museum. Vol. 26, No. 15 (3rd March, 1965): Cestoda (Tetraphyllidae and Trypanorhyncha) from Marine Fishes of New South Wales. By E. S. Robinson. Pp. 341-348. (Sydney: The Australian Museum, 1965.) 2s. [511]
- Occasional Papers of the California Academy of Sciences. No. 50 (September 15, 1965): A Review of *Kittoria*, a Genus of Diatoms. By A. L. Brigger and G. Dallas Hanna. Pp. 10. Proceedings of the California Academy of Sciences, Fourth Series. Vol. 30, No. 12 (September 15, 1965): New Species of Plants from Baja California, Mexico. By Prof. Ira L. Wiggins. Pp. 243-256 (5 plates). (San Francisco: California Academy of Sciences, 1965.) [511]
- Bulletin of the Museum of Comparative Zoology, Harvard University. Vol. 134, No. 4 (September 30, 1965): The Species *Bufo granulatus* Spix (Sallentia: Bufonidae) and Its Geographic Variation. By José M. Gallardo. Pp. 107-138. Vol. 134, No. 5 (September 30, 1965): The Mesopelagic Fishes Collected During Cruise 17 of the R/V *Chain*, with a Method for Analysing Faunal Transects. By Richard H. Backus, Giles W. Mead, Richard L. Haedrich and Alfred W. Ebeling. Pp. 139-157. (Cambridge, Mass.: Museum of Comparative Zoology, Harvard University, 1965.) [511]
- Current Tissue Culture Literature. A Key to the World Periodicals and Abstract Indexes, Vol. 5, Nos. 1 and 2 (June 1, 1965). By Margaret R. Murray and Gertrude Kopeck. Pp. 71. Annual subscription: 25 dollars. (New York, N.Y.: October House, Inc., 1965.) [511]

Progress in Spectroscopy

Unicam SP800 Spectrophotometer with automation accessories

*Save operator time, increase speed
and efficiency with Unicam
automation for:*

ENZYME REACTION RATES

**LIQUID COLUMN
CHROMATOGRAPHY**

**ALL ROUTINE ULTRAVIOLET
& VISIBLE SPECTROSCOPY**

Send for descriptive brochure.

Among the many important applications for the Unicam SP800 Spectrophotometer none is a better example of its potential than the measurement of enzyme reaction rates. For this the Automation Accessories are vital components. Other widely acclaimed features are the Flat Bed Recorder, the Beam Balance Smoothing Cam and the unique Second Sample Position, all of which mark the SP800 as the outstanding U.V. and Visible Recording Spectrophotometer. The Automatic Equipment provides:

AUTOMATIC interchange of up to 4 sample and 4 reference cells,
AUTOMATIC re-cycling over any pre-selected wavelength range,
AUTOMATIC recording at predetermined time intervals.

DIAMOND WHEEL CUTTING AND GRINDING MACHINE

THE MARK II UNICUTTA

The thin section machine quickly and efficiently produces thin sections for microscope study. Fitted with 6-in. dia. diamond cutting and grinding wheels.

Accessories for the machine:

- CAST IRON POLISHING PLATE
- NYLON SIMPLEX POLISHING PLATE COVERS
- EMERY DISC CLAMPING RINGS TO FIT EMERY DISCS TO POLISHING PLATE
- EMERY DISCS AND LOOSE ABRASIVES (Carborundum and Aloxite)

For full information, write or telephone:

Telephone: FINCHLEY 5978/9

CONSERVING THE NATURAL HERITAGE

AN impressive feature of the First Study Conference, "The Countryside in 1970", held in November 1963, was the range of the papers presented and of the reports of its several working parties and panels. This is equally true of the Second Study Conference held in London during November 10-12, 1965 (see p. 1265 of this issue). Its twelve study groups, whose work was initiated and co-ordinated by the Nature Conservancy, covered the training and qualifications of planners; the training and qualifications of the professions concerned with land and water; technology in conservation; countryside planning practice; outdoor recreation, both active and passive; traffic and its impact on the countryside; legislation; the preservation of natural, historic and other treasures; information and the countryside; living and working in the countryside; and the reclamation and clearance of derelict land. One panel was specifically concerned with the planning and development of the countryside in Scotland. The membership of the panels was representative and authoritative. Mr. E. M. Nicholson's review of the preparatory studies they presented shows how thoroughly the problems considered were tackled and that particular attention was given to the selection of priorities, to practicabilities and to timing in the light of further developments and enquiries since the previous conference.

The thoroughness of the preparation for this Conference is unmistakable, not merely from this review of the preparatory studies, but equally from the terms of reference of the study groups. This constitutes a major distinction from the First Conference two years ago, though it is possibly unfair to over-emphasize the very hurried preparation for that first conference, as is done in the review. Be that as it may, the first conference brought together for the first time many interested parties and made some advance towards a common understanding and a sense of common concern and a recognition of the opportunities for fuller co-operation. It did not lead to any adequate programme of action, and continuing reports in the interval from the Nature Conservancy and the National Parks Commission have indicated no decrease in their concern over particular threats to their responsibilities in the countryside. On the contrary, it has been substantiated by recommendations from the Town and Country Planning Association, and by the call for a Buchanan code to protect the countryside which came recently from a conference on roads and traffic in the National Parks, organized by the Friends of the Lake District, at Buxton. The reaction of the Botanical Society and the Northumberland and Durham Naturalists' Trust to the threat to Upper Teesdale inherent in the proposals of the Tees Valley and Cleveland Water Board, and very notably in the forthright report and newsletter, September 1965, issued by the Friends of the Lake District, have also added weight to the recommendations of the First Conference.

Throughout all this material there is a remarkable consensus of opinion as to the two critical needs of finance and of effective authority and power, failure in which respects has from the start intensified defects in organization that might otherwise have been less important or

insignificant. It is scarcely surprising, however, that this consensus of opinion should be reflected so largely and authoritatively in the conclusions and recommendations which the study groups made to the Second Conference. This is the more significant in that, as Mr. Nicholson explains, the subjects which the study groups tackled were limited in number, and priority was accorded to problems on which several different interests and organizations were ready to work with some prospect of producing realistic conclusions which might command widespread acceptance and thus be likely to be followed up effectively. Other factors which determined the selection of problems were suitable timing, the need for tackling issues of strategic importance for advances all along the line, the need to give the greatest possible impetus to improved communications, and co-ordination of the many diverse efforts within a more coherent and gradually emerging national policy for the countryside. The emphasis is on a series of simultaneous practical advances, expressing a new attitude and enabling it to develop faster and further in future.

Accordingly, this Second Study Conference began with an impressive stock of facts, of ideas and of well-considered proposals endorsed by people of impressive experience widely representative of the leading interests concerned. As suggested already, the varied and balanced membership of the study groups added greatly to the weight which their agreed reports could command on their inherent merits. Mr. Nicholson is fully justified in claiming that it can no longer be said that nothing can be done pending further investigations, or that the whole matter is too controversial for agreement among the main parties to be practicable. The main difficulty now appears to be not in reaching agreement but in getting action taken on the established facts.

Endorsement by the Conference of the proposals of the various study groups will create a new situation, in that the many and diverse interests in the countryside will have begun to come together, in something much larger than any of them, to ensure a fair and acceptable future for the countryside as a whole, within which each interest can find its place. If adequately sustained by public understanding and support, the new awareness, the new sense of common purpose and the new intimate contacts created by the Conference could maintain a new dynamic, leading to countless constructive actions, by individual or co-operative efforts. They must be supported, however, by vigorous and comprehensive measures in Parliament and by the provision of adequate resources by the Government, and no public protestations by the Government will dispense with its responsibility for finding Parliamentary time in spite of the heavy pressure of business.

Here may well lie the acid test of sincerity, and, welcome as was the presence at the Conference of one of the Ministers concerned—the Minister of Land and Natural Resources—that test has still to come. Its importance is demonstrated by the specific measures recommended for legislation not merely by the study group concerned with this aspect but also by those concerned with planning practice, the preservation of natural, historic and other national treasures and the Nuffield Enquiry into Common

Lands. They include, for example, the re-enactment, on a comprehensive basis in a new Town and Country Planning Act, of the so-called 'amenity clause', to be renamed the 'conservation clause', the removal of exemption from planning control of all 'sites of special scientific interest', and its modification in respect of agricultural and forestry buildings; the removal of any obligation for the Ministry of Agriculture to make ploughing grants in respect of such sites, and conferment on the Nature Conservancy of powers to make agreements with, and payments to, their owners. Also proposed are an amending Act to the National Parks and Access to the Countryside Act, 1949, incorporating the proposals of the National Parks Commission, but with the major new provision that the Commission should be reconstituted with nation-wide responsibilities for conserving fine landscape, co-ordinating surveys of outdoor recreation resources, designating a new category of "areas of special value for open-air recreation", and for ensuring the development of use of these resources with due regard to conservation and other interests. There are more than a dozen further specific proposals, but in sum they amount to the creation out of the National Parks Commission of a much stronger and more adequately supported (financially and in other ways) Countryside Commission, armed with more comprehensive powers.

These recommendations for legislation have been mentioned in some detail because they indicate the fundamental responsibility which rests on the Government and the key importance of adequate finance and of adequate powers if the Commission is to be effective. They also show that the Minister of Land and Natural Resources is only one of several Ministers directly involved and possibly not even the most important. Besides the Minister for Agriculture, those for Transport, for Power, for Housing and Local Government, for Education and Science, and for Technology, are deeply involved. Furthermore, the position has not been made the easier for the Minister of Land and Natural Resources by some of the recent changes in the structure of Government. Time has still to show how they will work in practice, but ostensibly the Ministry appears to be ill-served in the vital matter of advice. While the National Parks Commission falls within his responsibility, the Nature Conservancy now enjoys special status as a statutory Committee of the Natural Environment Research Council, which together with the other Research Councils falls within the Department of Education and Science.

The scientists working with the Nature Conservancy do not appear to be unduly disturbed by the change, and it is the quality of the advice on which the Minister appears to be relying that calls attention to the fact that a logical place for the Natural Environment Research Council would be within his Ministry. This weakness has, however, been highlighted by the Minister's own statement to the Second Conference, "The Countryside in 1970", and by the ineptitude of the second annual report of the Water Board, which was published by the Minister within a week of the Study Conference. Mr. Willey can surely not be unaware that his Ministry has already been strongly criticized, and not just by political opponents, for being unresourceful. He might have been expected to be on his guard against any further such charge, particularly as, when questioned in the House of Commons on November 1, he said that he hoped to indicate to the Conference the lines along which the Government was thinking. He had also stated on that occasion that due account would be taken of the results of the Conference and of the informal

consultations with representatives of the local authorities before submitting proposals to Parliament.

This was repeated by Mr. Willey in his statement to the Conference on November 12, but although he also said that he had been most impressed by what he had seen of the work leading up to the Conference, his statement gave no indication that either he or his advisers had paid any attention to that work or even to the results of the First Study Conference or to the present representatives of the Nature Conservancy or the National Parks Commission in their latest annual reports. The review of the work of the study groups was available at a press conference on November 3 and presumably to the Minister's advisers also, but there was no hint in his remarks that the crucial issues were recognized, either as presented there or in the many reports coming from other bodies.

It is in all these circumstances that the Minister's statement should be considered, and it says much for the restraint and good manners of the Conference that his statement should have been received without violent protest. Either Mr. Willey did not trouble to examine the evidence submitted to him, or he failed to appreciate the significant issues, for all that they have been clearly and emphatically reiterated in successive reports from the Nature Conservancy, the National Parks Commission and other bodies, independently of those coming from the working groups of the Conference itself.

The Minister's statement begins with the admission that Britain is now in a new situation which could not have been foreseen in 1949. His assertion that the National Parks Act of 1949 has been singularly effective in securing its objectives is certainly open to question. He admits, also, that there is a general consensus of opinion on the need for change, but that the Government is concerned merely to find the largest common measure of agreement on what ought to be done now and to limit its action to measures already long overdue, dealing with matters where continued inaction is causing harm. Even within this frame of reference, his statement is self-condemning: he limits his proposals to the care of the countryside and its enjoyment by the general public. By excluding consideration of the system of planning control and of the provision of the increase in financial support, which all are agreed is imperative, his proposals are ineffective and unworthy of serious positive discussion.

This is demonstrated by the paragraph which expressly excludes any major change in the administrative structure of the National Parks. In its endeavour to secure the co-operation of the local authorities to develop the National Parks, which undoubtedly is a cardinal condition of success, the Government omitted to write into the 1949 Act the establishment, for each Park, of a fully independent Planning Board, even when the Park lay within the area of several local authorities. Although, notably in the Peak District, this arrangement has sometimes worked surprisingly well, it was recognized from the start to be an administrative weakness, which was intensified by the failure to provide adequate financial support from national resources. This fundamental weakness was revealed in a glaring anomaly during the Manchester Water Inquiry, to which the report and newsletter of the Friends of the Lake District directed attention. Although the Lake District National Park Planning Board was whole-heartedly against Manchester's proposals, none of the Board's three planning officers was called to give evidence at the Inquiry in support of the Board's policy. These three planning officers are on the staffs of the three County Councils constituting the Board, and because

the county authorities differed in their opposition or objection to the proposed Order, none of the officers was called.

This example alone demonstrates the absurdity of taking seriously any legislative proposals which do not remove such a long-standing anomaly and provide the Planning Boards with their own planning officers, if not complete autonomy. Mr. Willey, however, appears to favour the continuance of the system of Joint Planning Boards where more than one county is involved. Although this system is fraught with weaknesses and drawbacks, he now proposes to extend the responsibilities of the Boards. Even on the financial side, he offers no more than that the additional administrative expenses directly involved in creating new facilities or improving the landscape should qualify for grant aid. The fundamental point is ignored that national issues and national responsibilities should be a prime charge on national resources and not, as at present, on local authorities, the financial resources of which are, in the nature of things, among the most limited of all the County Councils. Not even the legislative question, which was so clearly set out by a special study group of the Conference, is considered.

It is in this context that renders the Minister's statement and its proposals so derisory. He cannot even claim that his major proposal that the National Parks Commission should be reconstituted as a Countryside Commission with a new function of encouraging the provision of opportunities for enjoying the countryside generally has the support of the study groups of the "Countryside in 1970" Conference. The Countryside Commission there recommended would be much stronger and more adequately supported than the National Parks Commission and would be armed with more comprehensive powers and with effective administration at both national and local levels. These qualifications, which refer explicitly to legislative action, cannot be ignored without destroying the basis of the whole proposal.

Mr. Willey's concept of 'Country Parks', to be created by local authorities with Exchequer assistance in the countryside or on the coast, seems to pay no attention to the fundamental and vital issues on which urgent action is imperative if much of the countryside is not to be irreparably destroyed; this applies as much to the country parks now proposed as to the national parks and nature reserves. Nor does he show any wide vision, or deeper understanding, when he refers to forestry, to reservoirs, or to waterways. He promises that the Government will examine the findings of the report of the British Waterways Board on the future of the waterways, with reference to preserving for recreation and amenity those waterways which are no longer of importance for transport and commercial use; however, he gives no hint that the importance of waterways as a national resource in transport is generally appreciated. Even on derelict land and eyesores he says no more than that the Government has in mind legislation providing that expenditure by local authorities on derelict land should qualify for Exchequer aid, and that a programme should be drawn up, by consultation between the Countryside Commission and local authorities, to deal with places where removal of eyesores is specially urgent and where expenditure could restore a landscape of great attractiveness.

On traffic, Mr. Willey said that the powers in the 1949 Act to regulate road traffic in National Parks were out of date, and that it was proposed to amend the Act to bring these powers into line with the present needs of the

National Parks and to apply them, where necessary, to the Country Parks. In spite, however, of the wide and growing support for the policy of the Friends of the Lake District, who have urged the Minister of Transport and the Minister of Housing and Local Government to commission a species of rural Buchanan report on the traffic problems of National Parks, Mr. Willey gave no hint of any check to the present process of piecemeal 'improvement' and lack of consultation. The closure of the passenger train services between Ulverston and Lakeside, meanwhile, not only sacrifices an opportunity to relieve road congestion but aggravates the present severe congestion on the roads in the Lake District.

Mr. Willey made more encouraging remarks about the creation of long-distance footpaths and public access to open country, and hinted at the possibility of legislation to improve the situation. His Ministry is also considering the better use of our common land without waiting for further legislation, the lines of which are also being considered. He referred also to the need for further research into potential demands, and into the techniques of conservation and management, but, apart from the points already noted, the trend of the statement raises doubts as to how well the Minister is served by his advisers. These doubts are intensified by the recent annual report from his Water Resources Board, as well as by the unsatisfactory reply of the Secretary of State for Scotland to a recent question in the House of Commons regarding the feasibility study of the Solway Firth Barrage scheme. The Water Resources Board is itself in charge of the feasibility studies for the Morecambe and Solway barrage schemes and it was presumably on its advice that Mr. Willey based his reply. Even in its narrow view of them as potential sources of water supply, it appears to be far behind the times and unaware of the advice of the Nature Conservancy against locating resources in the hills and tapping water at the source. The advantages in transport, land reclamation, power and economics generally are ignored, not to mention the overriding importance of the results of such investigations being available at the earliest possible date if censured and unjustifiable decisions are to be avoided. The Board's shallow and obsolete thinking on the economic benefits of barrage schemes is paralleled by its inept remarks about the national parks.

These doubts are scarcely dispelled by the reply which Lord Mitchison, Joint Parliamentary Secretary to the Ministry of Land and National Resources, gave to a question in the House of Lords on November 16 regarding the feasibility survey of the Morecambe Bay Barrage scheme. Lord Mitchison said that the preliminary study now authorized to discover the quantity of water likely to be made available, the best way of making it potable, and the probable cost of making it available for use where required would take about 6 months and was unlikely to cost more than £15,000. The proposals for feasibility studies had been estimated by the consultants in July as costing £324,000 in the present and 3 subsequent years, or £80,000, £100,000, £90,000 and £54,000 in 1965, 1966, 1967 and 1968, respectively.

Lord Mitchison's reply makes nonsense of the reason given by Mr. W. Ross on November 3 for not proceeding with the full-scale trials immediately, and only brings to bear on the Secretary of State for Scotland the same criticisms which have already been made against the Minister of Land and Natural Resources. Whatever the extent to which his advisers have failed him, he cannot be entirely absolved from responsibility. He must, indeed, ask some of them to think again and quickly—especially

the Water Resources Board—for there is a strong case for bringing in others with a wider outlook and keener appreciation of the possibilities that exist to-day, alike for the utilization and the preservation of natural resources. Seldom, however, can a Cabinet Minister have confronted a meeting of the standing and authority of the Second Study Conference "The Countryside in 1970" with a brief so ill-prepared and irrelevant to the critical issues. For his own sake, to clear himself of the charge of incompetence and neglect, Mr. Willey must do some rapid and hard thinking before he prepares and presents his promised White Paper, or Parliament and the nation will be entitled to demand a change not merely of advisers but of Minister.

THE ROCKEFELLER INSTITUTE UNTIL 1953

A History of the Rockefeller Institute 1901–1953

Origins and Growth. By Dr. George W. Corner. Pp. 635+41 illustrations. (New York City: The Rockefeller Institute Press, 1965.) n.p.

FOR students of the history of science in the twentieth century *A History of the Rockefeller Institute 1901–1953* should be obligatory reading. For all of us who like to be reminded of great advances made in our life-time, it tells a fascinating story in which different parts of the puzzle are gradually fitted together to reveal a coherent picture. Dr. Corner has written a masterly account of a great Research Institute which was founded in New York in 1901 and has been intimately concerned with the spectacular advance of the 'life sciences' in recent years. He is an author distinguished for his scientific work as well as for his writing. He can describe the wide range of problems investigated at the Rockefeller Institute, without confusing us by the technical language of pathology, bacteriology, immunology and biochemistry, and he can interest us in the men as well as in their achievements. The typography and illustrations are worthy of the contents.

The Rockefeller Institute deserves such a volume, for it has played an essential part in the development of the natural sciences in the United States and of medical and biological science everywhere. The names of those who worked there and the subjects of their research recall many of the major advances in medical science in this century. It is of great interest, too, to learn how the Institute came to be founded, how its particular organization has suited different periods and different types of problem and of investigator, how it fared in the two great wars and how it has faced the recent expansion of scientific research and the tendency to substitute the team for the individual worker. In fact, Dr. Corner's history has lessons for all who may be concerned in the advance and the application of scientific knowledge, by research and by teaching, and under the aegis of Governments, universities or private institutions.

The Institute was founded by John D. Rockefeller, senior, advised by his almoner, Frederick Gates, and by his son, John D. Rockefeller, junior. Gates had been a Baptist minister for eight years and had then shown his great talents for organization as secretary of the Baptist Education Society. He came to Mr. Rockefeller in 1891, and soon acquired a poor opinion of current medical practice, of the efficacy of the medicines which were prescribed and of the theories on which they were based (whether by homeopaths or allopaths). He found that most of the medical schools in the United States had nothing to match the active research going on in universities or institutes in Europe. Here, then, was an opportunity for Mr. Rockefeller to use his great wealth in a most worthy

cause, for the relief of pain and sickness in the United States and throughout the world.

The proposal was accepted in 1901 and it was only natural to seek the help of Dr. Welch of Baltimore, already recognized as the leading authority on medical science and scientists in the United States. A board of directors was set up in 1902 and one of them, Simon Flexner, was made director of the Institute. There was still a farm of 13 acres for sale in the heart of New York beside the East River. It was bought for 650,000 dollars to provide a site for the permanent buildings: they were started in 1904 and Flexner began work in that year in temporary laboratories with the group of scientists he had collected with Welch's advice. It included Opie, Meltzer, Noguchi and Levene the biochemist, with some able people in junior posts and several voluntary workers, including Auer and Newton Richards.

Flexner made no attempt to follow the continental pattern of a research institute occupied exclusively on one kind of investigation. His staff were free to choose their own problems. Noguchi investigated snake venoms, Levene identified and analysed nucleic acids, Flexner worked on bacillary dysentery and on an epithelial tumour which he and Jobling had found in a rat and were able to transplant from one rat to another; he was soon to be widely recognized as the author of an improvement in the treatment of cerebro-spinal meningitis.

The new building, opened in 1906, had rooms for more men in the senior posts. Flexner and his advisers appointed Alexis Carrel, already well known for his successful vascular surgery, and Jacques Loeb, who came in 1910 to start a division of experimental biology. Meanwhile, the poliomyelitis epidemic in New York in 1907 had led Flexner to search for the source of infection, and in 1909, following a clue discovered by Landsteiner in Vienna, Flexner and his assistant, Lewis, succeeded first in infecting monkeys with material from fatal human cases and then in showing that the infectious substance could be drawn through a Berkefeld filter without losing its potency; that in fact it must be what is described as a filterable virus. Landsteiner and Levaditi made the same important discovery only a few days after Flexner and Lewis. It was not long before other discoveries were announced, for in 1910 Noguchi succeeded in detecting the spirochaete of syphilis in the brain and cord of patients with Tabes and general paresis, and Peyton Rous, appointed in 1909, found a transmissible chicken sarcoma which was caused by a filter-passing virus. In the same year the Hospital of the Institute was opened with a group of able young residents and a programme of research into five diseases: poliomyelitis, lobar pneumonia, syphilis, heart disease and 'intestinal infantilism' (coeliac disease). Judged by its immediate effects on the treatment of these diseases, the work done at the hospital may seem unrewarding, but we can now realize that some of it has played an essential part in the general advance.

The story of the attack on lobar pneumonia could, in fact, be used to point a variety of morals. It seemed for a time to be a story of wasted effort, when pneumonia could be cured by the use of antibiotics, but much of it can now be seen as having led to, or at least given strong support to, some of the recent developments of molecular biology.

The chemical investigation of the pneumococcus, conducted by Avery and his associates, showed that the immune reactions of the four known types of pneumococcus depend on the presence of particular polysaccharides in the capsule of the bacterium. In 1928, however, it was reported by Griffith in England that a harmless strain of living pneumococci became virulent when placed in contact with the dead remains of a virulent strain. Avery and his group found that the transforming agent appeared in a cell-free extract of the dead bacteria. By systematic fractionation they arrived at a practically pure substance of very high potency and this, in the end, proved to be a

nucleic acid of a type already studied at the Institute by Landsteiner and Jacobs and identified as deoxyribonucleic acid (DNA). It seemed, therefore, that a nucleic acid could be the effective agent in inducing heritable changes in a living organism, and, since this work was done, many investigators have shown that DNA is present in the chromosomes of higher animals and is a constant ingredient in the genes.

Avery's work on the pneumococcus was not completed until after his retirement in 1943, but much earlier the Rockefeller Institute had set up a branch at Princeton for the study of animal diseases, and here another chapter of the nucleic acid story had been added by J. H. Northrop and Wendell Stanley (who shared a Nobel Prize for it in 1946). Northrop had studied the chemistry of enzymes and found methods of crystallizing and purifying them. In 1936 he turned to the bacteriophages and was able to isolate a highly purified nucleoprotein which would invade a culture of streptococci and ultimately destroy it. He found that his phage material was actually a nucleoprotein containing ribonucleic acid, and it is now agreed that the bacteriophages are aggregates of nucleoproteins which replicate their substance by drawing on the host bacteria for the necessary ingredients. By that time Stanley, also at Princeton, had already succeeded in obtaining crystals of the tobacco mosaic virus and in showing that they were formed of some kind of protein molecules of very high molecular weight. Within a few years, Bawden and Pirie had shown that the active substance was not a simple protein but a nucleoprotein, with a nucleic acid fraction containing ribose.

These researches have helped to build up the present conception of living matter and the story of DNA and RNA, familiar to every schoolboy but still a wonder to his teachers. They have done so by introducing new techniques as well as by the facts they have established. But the Institute has many other investigations to its credit. Dr. Corner gives a full account of these and is able to show how the whole research programme of the Institute was helped by the progress in different departments. The two World Wars have chapters to themselves, with accounts of research on blood and blood substitutes, wound infection, shock and anti-malarial drugs. Another chapter deals with the retirement of Simon Flexner from his position as director in 1935 and the appointment of Herbert Gasser to succeed him. Dr. Corner's account of these two able and devoted scientists will show the reader why both were so well supported by their staff. Gasser's appointment came at a time when the effects of the Depression ruled out a policy of further expansion, but his many friends will be glad to realize how much was achieved in many fields of research under his direction. His retirement in 1953 brings Dr. Corner's history of the Institute to a close. It is a fine history: the world should be grateful to Mr. Rockefeller and to those who helped him to found and to run his Institute. It has increased our understanding of living things. The University which it has now become is increasing it still further and we can be sure that it will continue to do so. ADRIAN

EXPANDING HORIZONS IN OPERATIONAL RESEARCH

Proceedings of the 3rd International Conference on Operational Research, Oslo 1963

Edited by G. Kreweras and G. Morlat. Pp. xiv + 952. (London: English Universities Press, Ltd.; Paris: Dunod, 1964.) 130s.

IT is scarcely possible to mention operational research in general conversation without provoking the question "What is operational research and what does it do?" Many people will identify operational research with management science, but usually only a few well-informed

individuals will be able to distinguish it clearly from other branches of management science or to identify areas of research or types of problem to which the techniques of operational research can be applied.

The publication of the *Proceedings of the 3rd International Conference on Operational Research, Oslo, 1963*, may help to extend acquaintance with the subject among those who are not yet familiar with it. The book is intended primarily for the operational research specialist, both as a report of the conference and as a work of reference, but it also provides a wealth of informative reading for workers in other fields who are aware of the impact of operational research and who wish to keep abreast of the most recent developments. The volume runs to 982 closely printed pages and contains the text of more than 80 papers presented at the conference and reports of discussion. The international character of the conference is borne out by papers from fourteen different countries but the tendency for such conferences to be dominated by one or two countries remains. In this case more than half the papers came from the United States, France and Great Britain.

Operational research is characterized by the application of mathematical techniques to management problems. It is therefore not surprising to find an appreciable mathematical content in the book, but this should not deter the non-mathematician from reading it. Only a few of the sessions were devoted to specialized mathematical topics, while the greater part of the conference was devoted to the application of operational research in a great variety of civil, economic and social problems. One does not have to be a mathematician to appreciate this publication.

There is said to be a firm of operational research consultants whose definition of the subject is: "If we do it, it is operational research". This might have been the principle adopted by the organizers of this conference, for not only were there papers on well-established areas of operational research activity such as programming, scheduling, simulation, and forecasting, but also on less familiar operational research topics such as public health, traffic, research planning, long-term investment, national planning, agriculture and forestry and social organization. For this reason the book should appeal to a much wider readership than the specialist in operational research. It will serve to help workers in other fields to formulate their own empirical definition of operational research and to inform them of the impact which operational research is likely to make on their problems. The book should certainly appear as a reference work on the shelves of libraries catering for a great variety of interests.

In reviewing a book of this sort it is impossible to deal with the subject-matter and treatment of all the individual papers in sufficient detail to do each one justice. Also it is difficult to find an impartial basis for sampling the contents. In a review addressed to scientists it may prove acceptable to discuss only those papers presented at a session on "Research Planning" since this is a topic in which all scientists have an interest.

In the first of these papers, Eric Rhenman (Sweden) discusses the theories of planning and decision-making and observes that the most refined methods have only been applied to simple routine decisions, and not in important complex situations. He suggests a reason for this and urges closer contact with the emerging modern theory of organization. He warns operational research workers against the danger of attempting to derive algorithms when the problems are too complex for an analytical solution, and recommends an examination of the heuristics of practising research managers. In a much more mathematical paper, H. Theil (The Netherlands) makes a mathematical analysis of an idealized situation and considers the interplay of a decision-maker and research manager, when the goal of the former is to maximize a quadratic objective subject to linear con-

straints. In a paper by B. V. Dean (United States), on group research as an educational tool, the author discusses the advantages and disadvantages of group research (as distinct from research done by individual students). This will be of special interest to educationalists and others responsible for planning courses in which some form of applied research is an essential part of the curriculum. K. W. Webb (United States) reports on an exploratory operational research study of the United States national oceanographic programme, and makes the point that the experience that operational research has gained in the field of industrial management can be applied to good effect in the field of national management. He makes specific recommendations for work of an operational research nature to be continued in certain specific fields of oceanographic research. Perhaps one of his most important recommendations relates to the setting up of a scientific information system, with special attention to the information explosion that will take place because of continuous recording devices and sensor satellites. A paper by A. H. Rubenstein and M. Radnor (United States) deals with an investigation of the organization of research and development in decentralized companies and focuses attention on the relationship between top management and divisional management in the area of research and planning. Data from two field studies are presented. Finally, there is a paper by B. T. Price (United Kingdom) on the national control of scientific and technical resources, which takes the form of a contribution by someone who has not specialized in operational research, but wishes to find out whether it can help in the difficult problem of managing research and development at Government level.

This small sample of the subject-matter and content of papers presented at the conference should serve to attract the interest of scientists who are not directly concerned with operational research.

S. J. MORRISON

SHAPE AND ARRANGEMENT IN LIPIDS

The Structure of Lipids by Spectroscopic and X-ray Techniques

By D. Chapman. Pp. xu+323. (London: Methuen and Co., Ltd.; 1965.) 63s. net.

IT has frequently been observed that the investigation of lipids, once carried out by only a few patient investigators, has been revolutionized during the past ten years by the application of chromatographic techniques in general and of thin-layer and gas-liquid chromatography in particular. These procedures have solved many of the problems of separation and isolation which all lipid investigators have to face, and in recent years rapid advances have been made on problems where progress had been slow and a beginning has been made on problems which previously could not be started. These important developments must not be allowed to overshadow the less spectacular, but nevertheless important, developments recently made in our understanding of the shape and arrangement of the fascinating lipid molecules in crystals and in biological systems. Dr. D. Chapman has contributed to these advances and is well placed to describe for us the present situation.

Though it is now possible to isolate a lipid in a relatively pure state and to determine its structure and fatty-acid composition without too much difficulty, this tells us little about the arrangement of lipid molecules *in vitro* or *in vivo* systems, and advances in this area have developed from the application of those spectroscopic and X-ray methods which occupy the greater part of *The Structure of Lipids by Spectroscopic and X-ray Techniques*. It is made clear that there remain large areas of uncertainty and ignorance. This follows, for example, from the comparison between what is known about the long-chain

acids and their simple glycerides and the paucity of information concerning the more complex lipids. It is, of course, in the nature of science to start with simple and controllable systems, and to move from these to more complicated systems. Dr. Chapman has placed us in his debt by summarizing so effectively the answers to the simpler (relatively speaking) questions and by indicating the more difficult questions which still have to be solved. It is to be hoped that he will provide a sequel when further advances have been made.

After a brief chapter outlining the field of lipids, Chapter 2 (29 pp.) is devoted to the major separation techniques, including the use of the ultracentrifuge for lipoproteins, counter-current distribution, and the usual battery of chromatographic procedures. It seems to me that this chapter could have been omitted without serious loss. Apart from the final chapter ("Future Developments and Other Techniques", 5 pp.), the remainder of the book consists of six chapters covering the use of five spectroscopic techniques and of X-ray crystallography. The space given to each topic (ultra-violet spectroscopy, 15 pp.; infra-red and Raman spectroscopy, 81 pp.; mass spectrometry, 47 pp.; nuclear magnetic resonance spectroscopy, 48 pp.; electron spin resonance spectroscopy, 13 pp.; and X-ray diffraction, 95 pp.) reflects the present-day value of these various techniques. In each of these chapters a description of the basic theory is followed by a brief account of the experimental technique. Thereafter its application to carboxylic acids and related aliphatic compounds, glycerides, and, where relevant, sterol esters, phospholipids and other complex lipids, is described.

Figures and tables are liberally distributed throughout the book and add considerably to its value. Selected references are given at the end of each chapter and the index seems adequate but not over-long. Only a few minor errors were noted. There is no doubt in my mind that this is a valuable addition to lipid literature which chemists, biologists and medical men will want to have and will consult frequently.

F. D. GUNSTONE

COGNITIVE DEVELOPMENT OF THE YOUNG CHILD

The Early Growth of Logic in the Child

Classification and Seriation. By Bärbel Inhelder and Jean Piaget. Translated from the French by E. A. Lunzer and D. Papert. Pp. xxv+302. (London: Routledge and Kegan Paul, Ltd., 1964.) 40s. net.

THE gulf which, for forty years, has separated the work of Jean Piaget from the mainstream of psychological thought in the United States and in Britain is at last being bridged. Evidence of this is to be found in the new books which are appearing in Britain and in the United States, summarizing Piaget's work so far and attempting to synthesize it with recent developments in American and British psychology; and in Piaget's attempt to take account of the objections which are commonly, if sometimes rather uncomprehendingly, made to his methodology.

In such a context, translations of recent books by Piaget are to be welcomed, especially when the translation is of an unusually high standard and the book itself makes an important contribution to Piaget's theory of cognitive development. Not that *The Early Growth of Logic in the Child* is an easy book to read, even in its elegant translation. Nor does it make a good introduction to Piaget's work. (It is far too specialized for that, and the recent American texts by J. McV. Hunt and J. H. Flavell—read in that order—make a better introduction than anything written by Piaget himself.) But it is an important book since it provides a highly detailed description and explanation of the ways in which, according to Piaget, the logical processes of classification and seriation develop

in the young child: processes which are central to the attainment of the concept of number.

Piaget's orientation is a developmental one (or, as it is often termed, rather misleadingly, 'genetic'). He takes the position—contrary to that of American developmental psychologists such as Gesell—that, at any stage of development, abilities can be fully understood only by referring to their growth out of behaviour at an earlier stage. Thus, in the systematic errors, failures and omissions of the younger child are to be discovered the beginnings of the mechanism (or 'structure') which eventually enables the child to classify and to seriate without 'trial and error': abilities which are so facile in the average seven-year-old as to delude many non-Piagetians into taking them as given.

In their preface to the present book, Piaget and Inhelder imply that a reading of the conclusions section is virtually all that is required. "The main body of the work can be consulted as he [the reader] thinks fit, to find the justification for this argument or that. Finally (but only if he feels obliged to read the whole) he may turn to the introduction, to find out why these problems have been chosen." Even for the reader experienced in Piaget's writings, such a course of action is, I think, scarcely feasible. Piaget's habitual failure to define new terms in the appropriate place sees to that. (*A fortiori*, the reader new to Piaget will find that many terms peculiar to the system are defined only in the author's earlier texts.) Nevertheless, it might be wise to read the conclusions as a preliminary to tackling the main body of the work since experimental evidence on a number of investigations is presented in enormous detail.

A summary of these experimental studies is, of course, beyond the scope of a review such as this. Piaget and Inhelder not only trace the development of simple classification and seriation more thoroughly than any previous investigator but also investigate in detail the ability to deal with complementary classes, multiplicative classification (matrices) and multiple seriation. In each of these studies (most of which are broken down into a number of sub-problems) Piaget and Inhelder display considerable ingenuity in providing the child with meaningful problems which require physical manipulation for their solution and hence avoid the dangers inherent in relying on a merely verbal response.

One of the features of this book is that in it Piaget for the first time represents his findings in the form of statistical tables. This is certainly an improvement on the previous texts, in which it was impossible to tell how many cases Piaget had investigated before drawing his conclusions. But this innovation is—or should be—a long way from satisfying Piaget's critics. Just as many of them have failed to see the need to derive their hypotheses by first looking to see what is actually there (that is, Piaget's clinical technique), so Piaget still fails to come to grips with their basic criticism, the need for proper statistical tests of clinically derived hypotheses as distinct from the merely descriptive statistics contained in the book. Meanwhile, *The Early Growth of Logic in the Child* provides for those research workers such as Smedslund and Lovell, who are already attempting such a programme of testing, an unparalleled source of hypotheses concerning the development of classification and seriation.

J. H. DUTHIE

SEROTONIN

Serotonin

By Prof. S. Garattini and Prof. L. Valzelli. Pp. x+392. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 140s.

SEROTONIN is a comprehensive review of the available literature on serotonin, an amine usually referred to as 5-hydroxytryptamine in most scientific journals. As

such, it is a fine reference book which should be on the shelves of all who work with biogenic amines. Although serotonin was only truly discovered and synthesized about fifteen years ago, no fewer than three thousand six hundred literature references are included in this volume. Not only that—the book contains more than 30 tables in which are given the serotonin concentrations in various animal and vegetable tissues. The appendixes are also extensive—the first, on the distribution of the amine in Nature, occupies 30 pages; the second and third, on the effects of drugs and various treatments in relation to amine levels in animals, cover nearly 60 pages; the fourth, on drugs affecting the actions of serotonin, is contained in 16 pages; while the fifth (a very useful one) describes in 20 pages the distribution of many amines and enzymes forming or inactivating them in various parts of the brain of different animal species.

The first part of the book covers the biochemistry, physiological behaviour, localization and turnover of serotonin, and the pharmacology of the amine is contained in the second part. After reading the text, one has the impression that the authors have attempted to be critical in several sections; yet in other chapters this approach is entirely lacking and the reader is left bewildered by the mass of confused reports on a particular subject. Further, although the presence of serotonin in the nervous system is undoubtedly important, this should not completely overshadow the fact that serotonin and its metabolism are vitally concerned in the patient with a carcinoid tumour and even in the normal process of peristalsis.

The production of such a vast volume of data on serotonin has been no easy task, so one must not comment too much on presentation. However, references are sometimes confusing to the reader—for example, the reference numbers are in large size print in the tables yet in the text they appear as small upgrades. And this is not all the story, as reference numbers also appear in large size print in the text. An example is on page 112, lines 13 and 14, where reference 214 appears twice, each in a different form. It is more complicated when many reference numbers are listed (as on page 214, lines 12–14), and suggests that consistency has not been considered in this respect.

The book is printed in The Netherlands and is published on good paper. It will remain the major reference book on serotonin for some time to come. G. B. WEST

FIBRINOLYSIS

Fibrinolysis

By George R. Fearnley. Pp. xii+191. (London: Edward Arnold (Publishers), Ltd., 1965.) 35s. net.

FOLLOWING a lengthy period in the scientific wilderness, the fibrinolytic enzyme system now attracts the interest of biochemist, physiologist, pathologist, and physician. The resultant voluminous literature is scattered over a multitude of scientific journals covering a variety of disciplines. A monograph on fibrinolysis is therefore timely. The crescendo of interest in the fibrinolytic system would not be surprising if its function were so well-defined as that of the coagulation system. Its exact physiological role remains speculative, however, despite an accumulation of information on many of its facets. Its possible role in the prevention of fibrin deposition in blood vessels is one of the major reasons for the interest of the clinician in fibrinolysis and, as a clinician, the author has orientated his monograph, *Fibrinolysis*, in this direction.

After an account of the known components of the fibrinolytic system and their inter-relationships, the author discusses the methods used to assess overall blood fibrinolytic activity and the measurement of the individual components of the system. There follows an account of

the mechanism whereby the fibrinolytic system may remove deposited fibrin, and a discussion on the relationship between fibrinolysis and occlusive vascular disease. The changes in blood fibrinolytic activity produced by exercise, stress, fat meals, etc., are described. It may be argued that much of the quoted work in this section and, indeed, throughout the book has methodological weaknesses, but there can be little doubt that the use of these methods has contributed to knowledge about fibrinolysis. As the author says, "they are the tools of clinical rather than of fundamental research". There is a persuasive argument for the use of pharmacological enhancement of blood fibrinolytic activity in the treatment of thromboembolic disease, although evidence of therapeutic efficacy has still to be sought. No such enthusiasm is apparent for the use of thrombolytic therapy, and the author outlines the reasons why such therapy may be of little therapeutic benefit, particularly in occlusion of the coronary and cerebral vessels. There is a suitably brief account of the rare fibrinolytic states which occur in various pathological conditions. A chapter on the relationship between fibrinolysis and coagulation reinforces frequent pleas throughout the book that the two processes should be considered together; their separation into distinct entities loses sight of their probable interplay in a state of dynamic balance. A hint of the protean functions of the fibrinolytic system is provided by a chapter on fibrinolysis and inflammation and a chapter with sections on such topics as its relationship to cancer, renal disease, and immunology. The author finally discusses future developments by pointing out some areas of deficient knowledge and suggesting that their elucidation will require the participation of workers of several disciplines.

This unpretentious monograph is more than a mere aggregation of facts; the author adds a stimulating and sometimes provocative commentary. As befits one who has maintained an active interest in this subject for a decade and a half, he has drawn extensively on his observations. It is pointed out that the investigation of fibrinolysis has become so diverse that it is outside the scope of one individual to be competent and informed on all its aspects. For the non-clinical investigator this monograph will perhaps be disappointing since it is not, nor was it intended to be, a complete reference manual on fibrinolysis. It can, however, be warmly recommended to the general physician who wishes a readable guide to a relatively new subject. As an introduction to those intending to take up the study of fibrinolysis, it provides a valuable survey of practically every aspect of the subject, and its many suggestions for future research will help to channel effort into productive areas. D. OGSTON

NEUROTROPHIC PROCESSES

The Effect of Use and Disuse on Neuromuscular Functions

Edited by Ernest Gutmann and Pavel Hnik. (Proceedings of a Symposium held at Liblice, near Prague, September 18-23, 1962.) Pp. 576. (Amsterdam, London and New York: Elsevier Publishing Company, 1963.) 100s.

Mechanisms of Neural Regeneration

Edited by M. Singer and J. P. Schade. (Progress in Brain Research, Vol. 13.) Pp. v + 241. (Amsterdam, London and New York: Elsevier Publishing Company, 1964.) 80s.

IT has long been known that many organs tend to atrophy when deprived of their nerve supply; this has naturally led to the concept of a trophic influence of nerve fibres, which is thought to be conveyed either by special trophic fibres, or by the ordinary motor and sensory innervation. This kind of influence, whatever its true nature, acts in a very slow and intangible manner, and it was therefore somewhat neglected by experi-

mentalists while the more readily distinguishable electrical events accompanying nerve conduction and synaptic transmission were being analysed in great detail.

In recent years, however, the trophic processes have become of great interest to many biologists; if anyone should doubt this, he need only glance at these two large books. In the first symposium (first book), held in Czechoslovakia, sixty-six participants contributed nearly fifty short articles, covering a great variety of subjects. They have been classified basically into two main groups. The first covers the trophic function of the nerve cell, as reflected in long-term interactions between nerve and muscle. Here, one finds articles by Eccles, Gutmann, Mileti, Thesleff, Hnik and others, dealing with the properties of denervated and re-innervated muscle; further articles by Eccles, Szentagothai, Buller, etc., describe changes in the properties of muscle which follow re-innervation by foreign nerve fibres; and finally there is a discussion of axonal flow by Weiss and by Lubinska, as well as a somewhat less obviously relevant description by Hyden of neuroglial interactions.

The second main group is concerned with the effects of use and disuse on nerve and muscle cells. Most of the observations on nerve cells were made on spinal motoneurons (Asratyian, Eccles, Kostyuk, Beranek, etc.), but three articles by Hyden, Malcolm and Desmedt also describe experiments on cerebral neurones; in the final section, various aspects of muscle function and metabolism are considered by several authors, including Feng, Lissak and Shamarina. This book is full of fascinating information and interesting ideas; as usual, many questions are raised, the most glaring perhaps being that of the identity of the specific trophic factors which are generally assumed to be released by nerve fibres. There is, at present, scarcely any evidence about the kind of substances which are likely to be involved.

Although the second book is part of the now well-established series published under the general title of *Progress in Brain Research*, it is mainly concerned with changes observed in peripheral nerves. The approach here is much more didactic; there are only nine authors and their articles are based on lectures given at a summer school on brain research. Most of these articles are comprehensive reviews of selected subjects and they include extensive lists of references. Thus, although there is a substantial overlap with the Czech symposium, both in subject-matter and in authors (five authors are found in both books), the emphasis is mainly on processes of regeneration, and the tone and presentation are quite different.

There are three long reviews, by Lubinska on axoplasmic streaming, by Gutmann on neurotrophic relations and by Zelena on the degeneration and regeneration of receptor organs. Other substantial articles deal with intraxonal movements of phospholipids (Miani), the nerve growth factor and spinal regeneration (Scott and Liu), demyelination and remyelination (Webster) and some other aspects of the mechanism of regeneration (Trampush). Apart from a singularly obscure and unhelpful introduction (by the presumably overworked editors of this prolific series), most of the material has been clearly presented and it should be of much value to anyone needing detailed information in this field.

Both books have been well produced, with very legible print and with plenty of figures and tables, and each has an author index and a subject index; moreover, unlike the *Proceedings* of many other symposia, they have been published with commendable speed. Both books report a good deal of the informal discussions held during the meetings. Most readers will no doubt have their own views about the desirability of this rather general practice; to me, it seldom seems to add much substance to the main presentations, yet it must often contribute appreciably to the bulk and the cost and the delays of publication.

K. KRNEJVIĆ

Solid Circuits and Microminiaturization

Edited by G. W. A. Dummer. (Proceedings of the Conference held at West Ham College of Technology, June 1963.) Pp. 346. (London and New York: Pergamon Press, 1964.) 60s. net.

THE conference held at West Ham in 1963 made many sections of the British electronics industry more aware of the coming revolution in equipment design and technology. But too much must not be made of the implication, in the title of the conference, that the main driving force in the development of integrated circuits is the desire for large reductions in the size of equipment; reduced cost and increased reliability will often, singly or together, be greater incentives.

The *Proceedings* of the conference, informally written and informally presented to the reader, show a fair balance between the extension of the planar transistor technology to solid circuits, the relative merits of various logic circuits, the problems confronting the designer of analogue circuits, some new technologies such as electron beam machining, and several other important aspects of the subject. Packaging and interconnexions, however, are less well dealt with.

American developments have long dominated the subject and were given attention mainly by authors working in the European laboratories of the subsidiaries of American firms. But the *Proceedings* must now be seen against a recent issue (December 1964) of the *Proceedings of the Institute of Electrical and Electronics Engineers* which devoted about 340 pages to integrated circuits, giving a fairly comprehensive picture for mid-1964. Although even now the scope for improvements in materials, processing and assembly, for new active devices and for new outlets is very large, the stage has been reached when the customers of the industry can sample the products of the already extensive development programmes and study on an adequate scale the advantages accruing.

The rapid rate of advance in the field makes fairly frequent conferences very desirable, but greatly reduces the period over which any conference *Proceedings* continue to be reasonably up to date. This volume may, therefore, already be of little more than historical value.

J. R. TILLMAN

A Review of Sterilization and Disinfection as Applied to Medical, Industrial and Laboratory Practice

By Prof. Sydney D. Rubbo and Dr. Joan F. Gardner. Pp. xiii + 250. (London: Lloyd-Luke (Medical Books), Ltd., 1965.) 35s. net.

DURING the past ten years it has become increasingly obvious that many time-honoured methods used for sterilization in medical and hospital practice are either intrinsically inefficient or are rendered so by ignorance or inefficiency on the part of the operator. Nevertheless, very few hospital bacteriologists possess the necessary background knowledge to detect and correct these errors. It is for this reason that *A Review of Sterilization and Disinfection as Applied to Medical Industrial and Laboratory Practice* by Prof. Sydney Rubbo and Dr. Joan Gardner is all the more welcome.

Following chapters on the theoretical basis of sterilization, tests for its efficiency and the preparation of articles for sterilization, each of the usual sterilizing agents such as hot water, steam, hot air, radiation, filtration, gases and chemicals are described in considerable detail. The remainder of the book deals with special cases such as treatment of the hospital environment, the preparation of the skin or mucous membranes before operation, the treatment of pharmaceutical products and the sterilization of glassware and media used in bacteriological laboratories.

A great deal of useful information not easily obtainable is summarized in this way. This includes such diverse matters as tables giving the various indicators that may be used

to detect inefficiencies and the various faults that may develop in steam sterilizers, the methods used for the sterilization and preservation of pharmaceutical preparations, how to deal with discarded culture media and even a conversion table, which will be of particular value to anyone dealing with engineers who still persist in using the Fahrenheit scale.

Some of the opinions expressed by the authors may not be acceptable to everyone: this is perhaps inevitable, but adequate references are given to previous work so that anyone who is prepared to take the trouble can form his own.

The book is well produced, with a large number of diagrams and tables, together with an adequate index. It can confidently be recommended. R. HARE

Germes and Ideas

Routes of Epidemics and Ideologies. By Andre Siegfried. Translated by Jean Henderson and Mercedes Clarasó. Pp. viii + 98. (Edinburgh and London: Oliver and Boyd, Ltd., 1965.) 15s.

THIS book is based on a lecture given by Dr. Siegfried at the Clinique Médicale Propédeutique of Paris in 1958. It is an interesting example of the new outlook brought to a well-known subject by a wide and lively intelligence which had received no previous formal training in this field. Siegfried lectured on the routes followed by germs in the process of infection. In the first part he considers the geographical factors which dictate the routes, by caravan, by sea or by aeroplane, along which men, goods and germs travel. The germs tend to start from centres of infection in India, China or South America and to travel outwards, assisted by the speed of modern transport, hindered by modern hygienic and public health control. The spread of infection is then illustrated by accounts of the world-wide epidemics of cholera, Asian 'flu, plague and yellow fever. These are clearly and interestingly described for non-medical readers (probably medical readers would doubt whether there is danger of yellow fever being spread by cargoes of bananas bitten by infected mosquitoes). In the fourth part, Dr. Siegfried makes an interesting development by passing from the spread of germs to the spreading of ideas and propaganda. There is almost a suggestion that these are equally pernicious, and if they cannot be exterminated in their primary focus (as Simon de Montfort exterminated the Albigenian heretics) then they can often be kept out by an effective quarantine at the frontier (as practised in the U.S.S.R. and China).

This booklet contains interesting ideas, set out with French clarity and brevity. Besides students of medicine it should interest students of geography, history and sociology, bringing to their notice medical information in an attractive and comprehensible guise. The translation is good and lucid. F. HAWKING

Native Vegetation of Nebraska

By Prof. J. E. Weaver. Pp. 185. (Lincoln: University of Nebraska Press, 1965.) 4.75 dollars.

IN his latest book, Prof. Weaver, who is well known for his researches on prairie ecology, outlines for "the widest possible audience" the vegetation of the State in which he has worked for half a century. The native communities are straightforwardly described in turn, with a rather fuller ecological commentary for grasslands than for forests, and a final chapter is concerned with the cultivated crops of grassland soils. Vernacular names are used throughout, and their botanical equivalents are not given, not even in an appendix. There is no vegetation map, no index, and no list of the numerous illustrations.

D. R. HUNT

1965 NOBEL PRIZE FOR MEDICINE

By PROF. M. R. POLLOCK, F.R.S.

Department of Molecular Biology, University of Edinburgh

THE Nobel Prize for Medicine this year acknowledges the achievements over the past 15 years of three great French biologists: Prof. André Lwoff, Prof. Jacques Monod and Prof. François Jacob. It will be especially welcomed by molecular biologists as a highly appropriate recognition of the brilliant contributions of these scientists to our understanding of the mechanism of gene action in cell physiology. In this respect, it can be regarded as complementary to, and in some degree dependent on, the great discoveries of Dr. F. H. C. Crick, Prof. W. Watson and Prof. M. H. F. Wilkins, recognized by their Nobel Award of three years ago, which solved—at the molecular level—the problem of gene replication and laid the foundation for the formal solution of the nucleic acid code for sequences of amino-acids in proteins.

One need be no expert in this subject to appreciate the impact of the work of the 'Pasteur group', if one remembers that well-known terms in constant current use such as 'prophage', 'temperate', 'virulent bacteriophages', 'episome', 'structural', 'regulatory genes', 'permease', 'operon', 'messenger-RNA', 'allosteric proteins', etc., owe their origin to these three workers. Indeed, the concepts these terms represent, if not in every case entirely new, were defined, developed and made precise by them and their collaborators.

But, of course, their achievement ranges further and deeper than this by itself might imply. Its greatness is based, to a large extent, on the unique type of co-operation and cross-fertilization of ideas (perhaps 'complementation' might be a more appropriate description) arising from their three very different personalities.

Each of them would rank on his own as a scientist of outstanding talent. Though originally in the same department at the Pasteur Institute, they have seldom worked together in the same laboratory, and, unlike many successful research collaborators, only rarely plan the minutiae of experiments in continuous consultation.

Indeed, the circumstances and basis of how the members of this group (which was never a 'team' in any sense of the word) matured and developed towards an intellectual symbiosis make a fascinating story. It has often seemed that they came together almost by chance; certainly their co-operative work did not appear to arise from long-term conscious planning. Yet, it is difficult to believe that it could have happened without the encouragement and help originally provided, no doubt very consciously, by André Lwoff. François Jacob, trained in medicine, might perhaps be lingering in frustration in some antibiotics production unit (though one doubts it) and Jacques Monod might have fulfilled his earlier dreams and become an orchestral conductor. France might have had one more talented physician or even her Toscanini; but molecular biologists the world over would have remained the poorer for many years.

Lwoff, assisted by his wife Marguérite, had already, of course, achieved an international reputation in protozoology from work begun before the Second World War. This included their joint discovery of phosphopyridine nucleotide as the 'V' growth factor for *Haemophilus*, his theories on the independent genetic continuity of ciliate cinetosomes, and his thesis on evolution through loss of function.

Monod had discovered the phenomenon of biphasic growth ('diauxie') of bacteria growing on twin sources of carbon and energy in 1942. This, he found, was due to

the sequential utilization of the two carbohydrates present in the medium. His tentative interpretation had been in terms of the repression, followed by the induction, of the enzymes metabolizing the compound utilized last. From then on, he and his colleagues devoted themselves more and more completely to the elucidation of the fascinating problem of enzymic adaptation in micro-organisms. In 1950 it was still an open question whether this phenomenon was due to activation (or minor metabolic conversion) of a pre-existing inactive protein molecule, or to true *de novo* synthesis of enzyme from amino-acids. By 1954 he had succeeded (in collaboration with Cohn and Hogness) in showing that the process did indeed involve the biosynthesis of the whole enzyme molecule.

The 'great period' of the Pasteur group began only a little more than 15 years ago, following Lwoff's discovery that the genes of many bacteriophages could exist and multiply in two different alternative states: freely in the bacterial cytoplasm (leading to phage maturation and cell lysis) or integrated (as 'prophage') at a specific locus in the bacterial chromosome. It is encouraging for middle-aged research workers to realize, as they approach their half-century, that Lwoff was beginning his study of lysogenic bacteria (which previously had been little more than a biological curiosity) only a year or so before he reached his sixth decade. This has undoubtedly been his greatest scientific achievement so far. From it, the trail led, albeit somewhat tortuously, towards the formulation of two important biological concepts.

The first was that of 'episomes'—genetic entities which could be either extra-nuclear and partially autonomous or integrated as part of the chromosome, according to circumstances. This was developed by Jacob together with Elie Wollman, primarily on the basis of the phage/prophage interrelationship and their own observations on the semi-autonomous sex factor in *E. coli* (see later).

The second concept was that of 'cytoplasmic repressors'—a class of molecule responsible for specifically inhibiting the expression of a variety of genes. This was based, in the first instance, on two closely analogous phenomena: (a) the so-called 'zygotic induction' of prophage to free-growing active phage (discovered by Jacob and Wollman), which occurs after transfer of prophage, during conjugation, into a (non-immune) female cell not carrying prophage; and (b) the spontaneous production of β -galactosidase (for a limited period at maximal rate) which occurs immediately after transfer of the *inducible* gene during conjugation into a female cell carrying the 'constitutive' allele (discovered by Pardee, Jacob and Monod). In both instances reciprocal crosses had no such effect. This led to the notion that the donor cells, in both cases, contained in their cytoplasm an inhibitor responsible for blocking phage and β -galactosidase production respectively. The idea was developed mainly by Jacob and Monod.

In the early 'fifties, however, Jacob worked mainly with Wollman, whose critical mind contributed essentially to their remarkable success during the remainder of that decade.

In initial investigations of the autonomous, cytoplasmic *F* (sex) factor in *E. coli* (discovered independently by Hayes and by the Lederbergs and Cavalli in 1953), Jacob and Wollman elucidated its episomal nature by showing that it could be integrated into the chromosome and was thereby responsible for promoting the process of chromo-

some transfer during sexual conjugation. Their demonstration that the chromosome of *E. coli* is circular (broken only just before conjugation at the point where the sex factor had been incorporated) was really part of this discovery, since one of the two chromosomal 'ends' thus formed proved to be the leading point in its migration from the male to the recipient female, in which recombination occurs. By mechanical interruption of the mating process at different times after its initiation, they further demonstrated that there was a fixed order of entry of the various genes into the female cell. This order corresponded almost exactly to the order determined by the completely different method of measuring relative recombination frequencies of the chromosomal genes. It was thus a further confirmation of the validity of the classical mapping techniques which had been in use in all types of organism for several decades. Moreover, taken in conjunction with the demonstration that the chromosome was transferred from male to female at constant speed, it enabled the distance between genes to be measured in absolute terms (time units). Knowing the total amount of DNA present, this could be translated directly into lengths of DNA double helix.

During this period, Monod and his group were concerned primarily with defining and characterizing the so-called 'permeases'—specific enzyme-like entities, often inducible like ordinary enzymes and similarly controlled by genes with precise loci on the chromosome. They appear to function as energy-requiring pumps for transporting small molecules through the otherwise poorly permeable barriers of the cell envelope.

Although permeases have not yet been isolated or characterized at the molecular level, the idea that they could be regarded as entities in their own right has proved stimulating and useful. Moreover, the study of permeaseless ('cryptic') strains and mutants clarified a number of perplexing problems in cell enzymology.

It was not until 1957 that Jacob and Monod began their famous collaboration, with the demonstration (together with Pardee) that in *E. coli* strains diploid with respect to the β -galactosidase locus the wild-type character of inducibility usually completely suppressed the (mutant) character of constitutivity, and never vice versa. This was powerful evidence against the frequently discussed possibility that enzyme production might be due to direct stimulation of gene function by a specific inducer (endogenous in constitutive strains). It strongly indicated that enzyme induction, just like the induction of prophage (in lysogenic bacteria) to the free-growing, active phage state was essentially a release from inhibition. The fact that the R^+ genome (showing the property of inducibility) inhibited the expression of the R^- (constitutive) mutant allele in the *trans* position (that is, across the physical gap presumed to separate the two homologous chromosomes of the diploid) suggested that the suppressing effect was due to a diffusible molecule. The idea of specific cytoplasmic repressor substances being primarily responsible for control of gene expression was thus further developed.

During the next few years, Jacob and Monod defined, studied and characterized (one might almost say 'promoted') the following important biological entities, many of which have since received further experimental substantiation from other laboratories.

(1) *Regulatory genes*, specifically controlling the rates of formation of proteins, as distinct from *structural genes*, responsible for determining their amino-acid sequences.

(2) The *operon*, consisting of a cluster of genes, arranged contiguously along the chromosome, being concerned with one particular metabolic function (such as the formation of enzymes catalysing the biosynthesis of an amino-acid) and expressing themselves co-ordinately, being switched on and off together, under the control of a single regulator gene.

(3) *Messenger-RNA*. Not entirely a new idea, of course, and investigated by many other molecular biologists,

but illuminated by the work of Monod and Jacob and their associates in a characteristically impressive fashion. According to them, it embodies the properties of a relatively labile and rapidly produced carrier of information from the gene to the rest of the cell, by its action as a template for protein synthesis.

Their work together culminated in the classic paper published in 1961 in the *Journal of Molecular Biology* on "Genetic Regulatory Mechanisms in the Synthesis of Proteins". In this they outlined their famous hypothesis on the mechanism of control of genetic expression through the action of a series of specific cytoplasmic repressor substances. In the case of induction of a particular enzyme, it is supposed that the regulatory gene produces a repressor molecule which, by combining with a specific chromosomal locus (the 'operator') located at one end of the operon, inhibits transcription of the operon genes into messenger-RNA, so that synthesis of the relevant proteins is suppressed. The role of the inducer is to inactivate the repressor. With repressible enzymes, the production of which is normally inhibited by the compound they synthesize, the product of the regulatory gene is supposed to become activated as a repressor only after combination with the end-product ('co-repressor') molecule.

The essence of this theory is that the information provided by the small effector molecules involved in enzyme induction or repression is a 'switch impulse', transmitted through the activation or inactivation of a specific pre-formed inhibitor of the expression of a predetermined genetic sequence. Thus, one of the most important mechanisms by which the environment can 'mould' the physiology of the cell towards more effective performance in a given situation is by the 'uncovering' of genes in their role as blue-prints for the synthesis of the relevant enzymes. The pattern that is changed by an alteration in the environment is thus the relative amounts of different enzymes present in the cell and not their chemical structure. This is now generally accepted as one of the fundamental bases of biological adaptation processes at the cellular level.

However, the hypothesis, in its detailed form, is far from proved. It must be remembered that cytoplasmic 'repressors' have not yet been isolated in any form, nor have their effects been directly demonstrated. Like permeases, they do not yet have molecular reality. Moreover, it is uncertain how complete the model is, even for *E. coli* β -galactosidase. And it is still largely a matter for conjecture how far it may be extended to living systems beyond the bacteria and certain other species of micro-organism. For example, it could clearly be applied to embryonic differentiation; but even if differentiation is based on a sequential expression of various portions of the genome, triggered individually by inducers and repressors, the theory does not by itself indicate by what mechanism the 'control' genes are themselves controlled. Is it simply the structural genes themselves—acting through the inducing or repressing properties of the metabolites the production of which they activate? Or is there some new entity still waiting to be discovered—a master regulatory gene, perhaps, with an endogenous rhythm or maturation-pace 'of its own'? The speculative 'regulatory circuits' outlined by Monod and Jacob are interesting attempts to give some idea of how interrelated control systems might be built up on the basis of their main hypothesis. The irreversibility of differentiation processes can indeed be thus modelled. But the authors would probably be the first to admit that they have not yet provided a satisfactory answer to the problem of the time sequencing that is inevitably involved.

On the other hand, there is no doubt that the theory has had a profound influence on the trend of biological thought during the past four years and has been of immense importance in stimulating much valuable experimentation, as well as in providing a model for workers investigating regulation processes in many types of biological system.

Monod, together with Changeux and Wyman, has now plunged deeply into the problem of enzyme function, in elaborating the concept of 'allostericity' in proteins. This principle is based on the Bohr effect and O_2 -dissociation curves of haemoglobin, and on the more recently observed phenomenon of 'feed-back inhibition' of certain enzymes by the end-products of the metabolic chain which they have initiated (discovered by Novick and Szilard, and by Umbarger). The essential idea, which has already received considerable support, is that the functioning of the active site in an enzyme can be specifically modified by combination with another type of molecule (chemically unrelated to the normal substrate) at a different site. In this way, the function of an enzyme can be specifically controlled, with immediate effect, by direct action and not only by influences on its rate of biosynthesis. The mechanism of what Monod has called 'allosteric transitions' involves reversible switches between alternative conformational states in the structure of the enzyme. He believes it must often, if not always, depend on the molecule being oligomeric and having bilateral symmetry. Certainly, most enzymes that show the phenomenon do consist of a number of (often identical) polypeptide chains. It offers a reasonable teleological explanation of why enzymes are often such large, polymeric molecules.

Furthermore, as Monod and Jacob have often emphasized, their hypothetical 'cytoplasmic repressor' must also possess the property of 'allostericity' in order to exhibit the character of interrelated reactivity with both the effector molecule and the operator locus. Indeed, it is difficult to avoid the conclusion that it was just this particular character, with which the repressor molecule had to be endowed in order for it to fulfil its role in the Monod-Jacob scheme, that led them to search for analogous properties in other, more concrete, types of molecule. If so, it is a fascinating example of the ironic way by which man can make his great discoveries. A purely logical necessity involving the postulate of a new type of property in a purely hypothetical molecule leads to the search for, and discovery of, just this property—observed but hitherto not adequately recognized—in a whole range of concrete and well-defined substances. But it is probably best not to try to recapitulate the mental processes involved. The results by themselves justify the method, whatever it may be. Although in some ways less complete and less precise than the other hypotheses, this may ultimately prove to be the most useful of them all.

But this cannot be the end of the story. There is still plenty of time ahead for further discoveries, and one wonders what new natural phenomenon—observed, no doubt, but not yet properly appreciated or understood—will be the next to blossom under such patronage.

All this work has rightly been regarded as typical of the 'French' approach at its best: what has been called the 'hypothetico-deductive' type of reasoning, which many believe to be the only satisfactory method of argument in science. But in their case (as in so many others) it is

surely the method of presentation, rather than the method of thinking or reasoning, that stands out so clearly as 'hypothetico-deductive'. It is difficult to believe that something akin to a process of induction from observations that have often been made fortuitously has not contributed importantly to their discoveries.

The work of the 'Pasteur group' has, inevitably, been subjected to the criticism that would be expected from those who do not understand what molecular biology is about, or who are envious of its great achievements. They have been accused, by many old-fashioned morphologists and by neo-vitalists of the twentieth century, of having an oversimplified or mechanistic approach.

On the other side, chemists, and even some biochemists, have been distrustful of interpretations made at the molecular level, which often do not involve identification and isolation of a known type of compound, or the specific demonstration of its action in a chemically defined system.

More seriously, there has developed in some quarters a resentment at what has been taken to be an inflexibly dogmatic attitude which is too impatient of criticism or alternative hypotheses. Certainly the devastatingly brilliant disposal of "objections from the floor" in open conference, which is characteristic of this outlook, would scare off all but the most confident contestant. But in private discussions among themselves, and in *tête-à-tête* conversations with colleagues, there is often so sweet a reasonableness that criticism is disarmed. Few visitors to their laboratories in the old days failed to fall under the spell of the charmed atmosphere in the Service du Physiologie Bactérienne—though it might have been only a matter of minutes since they had been hacked to pieces in one of those well-known seminars.

Nevertheless, there is perhaps substance in some of this anxiety—in the sense that too great an intellectual dominance and too brilliant an advocacy in promoting a theory can dazzle the originality out of other workers and stop people thinking. Far too much may then be taken for granted. But it would have to be admitted that, great experimentalists though they may be, it is just this ability to clarify an issue, define the problems, contrast and evaluate alternative interpretations, and finally to offer a precise all-embracing hypothesis (not necessarily entirely original or totally satisfying: how could it be?) that Lwoff, Monod and Jacob have been able to offer most to science. It is interesting that this has, indeed, been specifically recognized in their Nobel Award citation.

Moreover, they usually expound their ideas in papers written in an English that (it must reluctantly be conceded) is not only grammatically impeccable, but has a beauty of style and clarity of expression that an Englishman would be almost ashamed to contemplate, were it not such a pleasure to see our native language prove itself to be so fine a vehicle for the communication of ideas.

BIOCHEMISTRY AND MENTAL FUNCTION*

By PROF SEYMOUR S. KETY

Chief, Laboratory of Clinical Science, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

IF we are ever to understand and rationally to meliorate the disturbed processes which underlie mental illness, it will be by investigation of the clinical problems themselves and examination of the mental, social, neural and biological elements which comprise behaviour. It is all of these which the Americans call 'psychiatric research',

and in Great Britain, the Mental Health Research Fund has added much to its vigour for more than a decade.

Although they are not alone in their importance to psychiatry¹, the biological sciences have a significance which is not attenuated by community with the social and psychological sciences, nor is their power less real by having been only partially demonstrated. It is the area, tentative as yet, between biology and human psychology

* Substance of the Third Mental Health Research Fund (38, Wigmore Street, London, W.1) Lecture delivered on February 26.

that I have chosen to dwell on, and I shall do so largely in terms of the work of my associates and myself in the Laboratory of Clinical Science at the National Institutes of Health, Bethesda, without any pretension that this will constitute an adequate review of a growing field.

The time is not yet at hand, if, in fact, it will ever be reached, when one can speak meaningfully of the biochemistry of mental state. There are, however, a few areas where one can see the beginnings of correlations and significant interrelationships and these include consciousness, intellectual function and affect.

My interest in consciousness goes back to the Science and Philosophy Club at the Central High School in Philadelphia, a club which bore the brave motto "*Felix qui potuit rerum cognoscere causas*", and in which a great teacher, Edwin Landis, introduced us to Berkeley, Mach, Eddington, and the fathomless problem of the nature of consciousness. Many years later I was introduced to the cerebral circulation by Carl Schmidt, through his definitive work in the rhesus monkey, and began to feel how much might be learned from measurements in man, whose brain, with its subjective wealth, and whose diseases could not be replicated in animals. Making use of some fundamental principles of inert gas exchange, the Fick principle, and a little calculus, which there is no time to discuss in any detail, we were eventually able to make what still appear to be satisfactory measurements of blood flow, oxygen and glucose consumption in the conscious human brain under a variety of physiological and pathological conditions. In Table 1 are presented some normal values representing, in fact, the average of the first investigations of healthy volunteers of about twenty-five years of age². Measurement of glucose consumption followed later, confirming the thesis that the major substrate for oxidative energy in the brain is glucose, the utilization of which represented an almost stoichiometric equivalent of the oxygen consumed. From these measurements it was possible to compute the rate of energy utilization by the human brain which turned out to be close to 20 W. In comparison with the enormous expenditure of energy which modern computers require, this represents a remarkable degree of efficiency and miniaturization.

Table 1. OVER-ALL BLOOD FLOW AND ENERGY METABOLISM OF THE NORMAL HUMAN BRAIN

Blood flow ml./100 g/min	54
Oxygen consumption ml./100 g/min	3.3
Respiratory quotient (CO ₂ /O ₂)	0.99
Glucose consumption mg/100 g/min	4.9

We were anxious to examine states markedly different from the normal in functional level and chose states of altered consciousness (Table 2). It was quite apparent that there was a rough correlation between level of consciousness and over-all oxygen and energy utilization by the brain³. In anaesthesia, for example, where the cerebral oxygen consumption was reduced by 40 per cent, there appeared to be support *in vivo* to the earlier *in vitro* investigations of Quastel⁴, who had shown that anaesthetics interfere with the oxygen consumption of brain slices. But all these data merely tell us that the oxygen consumption and energy-level of the brain are reduced in states of depressed consciousness; they do not explain the coupling between function and metabolism which is one of the most interesting topics of present concern. One could argue that the primary effect in any of these conditions was on the metabolic 'power supply' of the brain necessary for the maintenance of consciousness. An alternative hypothesis, however, would be that the primary site of interference was in the interaction between neurones at the synapses, which once inhibited, depressed both the functional activity and the energy requirements of the system. This interesting problem of the coupling between function and metabolism must await clarification by the work of those like McIlwain, Rodnight, Larrabee and Chance, among others.

Table 2. CEREBRAL OXYGEN CONSUMPTION IN STATES OF DEPRESSED CONSCIOUSNESS (EXPRESSED AS PERCENTAGE OF THE VALUE IN HEALTHY YOUNG MEN)

Senile psychosis	82
Diabetic acidosis	82
Insulin hypoglycaemia	79
Surgical anaesthesia	64
Insulin coma	58
Diabetic coma	52

Table 3. CEREBRAL OXYGEN CONSUMPTION IN VARIOUS MENTAL STATES (EXPRESSED AS PERCENTAGE OF THE VALUE IN NORMAL CONTROL STATES)

Normal sleep	97
Schizophrenia	100
LSD psychosis	101
Mental arithmetic	102

There are states of altered consciousness, however, in which such a neat correlation with total cerebral metabolism and energy does not exist (Table 3). Normal sleep is one such state; the poetic description of the wakening brain by Sir Charles Sherrington in "Man on His Nature" is well known:

"Suppose we choose the hour of deep sleep. Then only in some sparse and out of the way places are nodes flashing and trains of light-points running . . . the great knotted headpiece of the whole sleeping system lies for the most part dark. . . Should we continue to watch the scheme we should observe after a time an impressive change which suddenly accrues. In the great head end . . . spring up myriads of twinkling stationary lights and myriads of trains of moving lights of many different directions. . . the great topmost sheet of the mass, that where hardly a light had twinkled or moved, becomes now a sparkling field of rhythmic flashing points with trains of travelling sparks hurrying hither and thither. The brain is waking and with it the mind is returning."

Not only did our results⁵ force the rejection of a simple cerebral ischaemic theory for sleep which dated back to Alcmaeon; they challenged as well the generally accepted 'Sherringtonian' notion which equated sleep with neuronal inactivity. More recent neurophysiological findings are more consonant with what we learned about the nature of sleep. Evarts⁶, in very elegant investigations of the activity of individual neurones which he has observed through microelectrodes chronically implanted in the cortex of unanaesthetized cats, has found no net decrease in cortical neuronal activity during natural sleep. He has, on the other hand, demonstrated characteristic alterations in the activity of individual neurones or groups of neurones, some showing inhibition when the animal sleeps, but others coming into greater activity at that time.

The results in schizophrenia⁷, during LSD psychosis⁸ or in mental arithmetic⁹ all reinforce the concept that the brain, unlike the heart or the liver or kidney, is an organ for computation and communication. In such functions there is no necessary correlation between the energy utilized and the efficiency of the process or the quality of the output. To differentiate these alterations of consciousness in terms of the cerebral oxygen consumption would be like trying to correlate the nature of a radio programme with the power used.

Some of our more recent investigations have attempted to examine the energy utilization of many structures within the living brain. The first approach to measurement of oxygen consumption is in defining the local perfusion rates. Using basic principles similar to those of the nitrous oxide method, we have related the quantity of an inert diffusible substance taken up by a small tissue region to its perfusion¹⁰. If the tracer is radioactive, one can measure its uptake during a standard time interval in the various structures of the brain by autoradiography. In the autoradiogram, density is related to the concentration of tracer which in turn can be related to the blood flow during the physiological state just prior to the abrupt killing of the animal. Under most physiological conditions there is reason for believing that the blood flow is determined by the oxygen consumption, so that in a rough way the autoradiographic density gives information

on the differential energy utilization in various structures of the brain. Such investigations have revealed a remarkable differentiation of cortical blood flow in the unanaesthetized brain with the primary sensory areas showing far greater activity¹¹. This differentiation does not appear to be present in the brain of the foetus or the neonate. Anaesthesia obscures this differentiation, reducing the areas of greater cortical oxygen consumption to a relatively homogeneous average value, while there is evidence that sensory stimulation results in a recognizable increase in blood flow and, presumably, oxygen consumption along the appropriate sensory pathways¹².

The maturation of intellectual function and its maldevelopment depends on many processes in addition to oxygen consumption. In 1949, when Sokoloff first became associated with us, we undertook an investigation of cerebral blood flow and oxygen consumption in patients with hyperthyroidism. This resulted in the quite surprising finding that although the total oxygen consumption of such patients was markedly elevated, there was no significant increase in the oxygen consumption of the brain¹³. These results demonstrated that the effects of thyroid hormone were not uniformly applied to the metabolism of all cells in the body. A finding such as this requires an explanation and Sokoloff set about to find one. Using radioactive thyroxine he learned that the hormone crossed the blood-brain barrier and was available to the cells of the brain. He knew also that the brain was peculiar, in that its oxidative processes were almost entirely confined to a single substrate, glucose, and that, although Richter, Waelsch and others had demonstrated an active protein synthesis in the mature brain, that process was still considerably slower in brain than in liver and could scarcely account for a significant fraction of the cerebral oxygen consumption. These considerations led him to the hypothesis that thyroxine neither stimulated oxidative metabolism directly nor uncoupled it from phosphorylation (which were the prevailing concepts) but acted on some specialized process such as protein synthesis.

In 1954 he came to the National Institute of Mental Health and began a highly productive collaboration with Kaufman. In 1959 they were able to report that L-thyroxine, administered to normal animals *in vivo* or added directly to the incubation medium *in vitro*, stimulated the rate of amino-acid incorporation into protein in cell-free, rat liver homogenates. This stimulation of protein synthesis *in vitro* occurred in the absence of changes in oxygen consumption or oxidative phosphorylation. They further suggested that the characteristic effects of thyroxine on energy metabolism were secondary to the stimulation of reactions which required energy such as protein biosynthesis¹⁴.

The mitochondria are clearly involved in this process since it is these structures alone rather than the microsomes or the cell sap which differentiate hyperthyroid rats from euthyroid controls in the ability to stimulate amino-acid incorporation into protein¹⁵. Thyroxine in the presence of mitochondria and an oxidizable substrate apparently produces a soluble factor that can be isolated and which will in itself stimulate protein synthesis. The evidence indicates that this factor stimulates the transfer of sRNA-bound amino-acids into microsomal protein^{16,17}. Much remains to be done in identifying the factor and further defining its action on the microsome and the precise step in protein synthesis at which it occurs. The demonstration of a stimulation of protein synthesis by thyroxine, however, clearly defined as it is by *in vitro* investigations and confirmed *in vivo*, appears to be the fundamental mechanism of action of this hormone and explains much of its physiological effects.

Recently, Sokoloff, in collaboration with Klee¹⁸, has re-examined the effects of this hormone on the brain. Although thyroxine does not stimulate protein synthesis in mature brain, explaining its failure to increase cerebral oxygen consumption in adult man, it does so significantly

in neonatal brain, and again it is the mitochondria which differentiate the two.

These findings help to explain the well-known clinical effects of the thyroid hormone on the development of the brain and of intellectual function in infants compared with its relatively minor effects on these functions in the adult. They corroborate and offer a mechanism for Eayrs's finding of the requirement for thyroxine in the dendritic proliferation of immature cerebral cortex. Thus, this work forms a crucial link between the absence of thyroid hormone and the retarded cerebral development in cretinism.

In 1956, soon after the Laboratory of Clinical Science, National Institute of Mental Health, was organized, some of us became interested in the cluster of thought disorders which is called schizophrenia, and gave attention to the hypothesis which attempted to explain many of the mental symptoms of schizophrenia on the basis of an abnormal degradation of circulating epinephrine to abnormal oxidation products such as adrenochrome or adrenolutin¹⁹. That hypothesis seemed especially plausible because it took cognizance of the evidence for genetic factors as well as the importance of stressful life experiences in the pathogenesis of the mental disorder. The difficulty in testing the hypothesis lay in the lack of knowledge concerning the normal metabolism of epinephrine, let alone its possible abnormality in schizophrenia. In 1956 one could account for some 5 per cent of administered epinephrine which was excreted unchanged in the urine, while the remaining 95 per cent was disposed of by unknown mechanisms.

Isotopic techniques, which had been so valuable in the tracing of other metabolic pathways, were not readily applied to this problem because the pharmacological potency of epinephrine prevented the administration of enough of the hormone labelled with carbon-14 which was then available to permit characterization of its products. It was apparent that to use isotopic techniques to advantage for studies of the metabolism of epinephrine, especially in man, would require an isotopically labelled epinephrine of unheard-of specific activity. We were finally successful in having a few millicuries of 7-³H-epinephrine synthesized. The tritium label made possible the high specific activities required, while its position at C7 met our expectation that the label would be retained through the various possible metabolic degradations.

In 1957, Armstrong, McMillan and Shaw identified the first major metabolite of epinephrine (vanillylmandelic acid, VMA, or 3-methoxy-4-hydroxymandelic acid) in the urine of a patient with pheochromocytoma and in normal urine²⁰.

A few years before, Julius Axelrod had joined the Laboratory, bringing with him great interest and competence in the catecholamines. Although the metabolism of adrenaline to VMA was generally regarded as involving first deamination by monoamine oxidase and then *O*-methylation, Axelrod, on the basis of pharmacological and biochemical evidence, postulated the existence of an alternative pathway with *O*-methylation as the first step followed by deamination. He then proceeded to demonstrate in the urine the existence of that hypothetical compound which he designated "*O*-methylepinephrine" or "metanephrine", a second major metabolite of epinephrine²¹. He described and characterized the enzyme responsible for this conversion (catechol-*O*-methyltransferase) and the requirement of *S*-adenosylmethionine as the methyl donor²². He suggested that *O*-methylation rather than deamination was the principal enzymatic process involved in the inactivation of circulating epinephrine and later went on to show that norepinephrine was metabolized through completely analogous pathways by the same enzymes²³. Fig. 1 shows the present state of knowledge of the metabolism of these two catecholamines with a number of additional minor metabolites which Axelrod *et al.* have identified. Together all these metabolic pro-

ducts account for some 98 per cent of administered epinephrine or norepinephrine and, presumably, a similar accountability would hold for these substances when they are released into the circulation under physiological conditions.

With the background of information on the normal degradation of the hormone which was thus provided, it was then possible to examine the metabolism of epinephrine in schizophrenic patients and normal volunteers using the tritium-labelled substance^{24,25}. We were unable to find any evidence for a significant abnormality in the metabolism of intravenously administered epinephrine among the schizophrenics either qualitatively or quantitatively, the four normal metabolites and the unchanged hormone accounting for 98 per cent of the tritium in the urine in both groups of subjects.

The synthesis of tritiated epinephrine which was stimulated by that hypothesis but, most important, the work of Axelrod *et al.* have, however, had important implications for psychiatry. The identification of the metabolites of epinephrine and the development of methods for their estimation in urine make it possible to obtain information on the secretion of this hormone in a variety of physiological and pathological states and in response to drugs. Investigations by Axelrod and Kopin,

among others, with norepinephrine were a logically related step, and in the past few years the storage and release of norepinephrine at the sympathetic nerve endings and the factors which control these processes have become one of the most exciting fields of pharmacology²⁶. The insights which such investigations have given us into the possible actions of drugs which affect mood will be discussed later.

Thirteen years ago Osmond and Smythies, in conjunction with Harley-Mason²⁷, advanced the interesting hypothesis that there was an accumulation of an abnormal methylated compound with hallucinogenic properties in schizophrenia. They were led to this possibility by the fact that the potent psychotomimetic drug, mescaline, was almost identical with trimethylated dopamine. In the same communication Harley-Mason pointed out that the dimethyl derivative (3,4-dimethoxyphenylethylamine), which had interesting behavioural effects, could possibly be formed by transmethylation *in vivo*. In 1961, Pollin, Cardon and I²⁸ tested this hypothesis by observing the mental effects of methionine given orally to a small number of chronic schizophrenic patients who had been maintained on a monoamine oxidase inhibitor. We reasoned that under those conditions it was conceivable that the levels of *S*-adenosylmethionine, which Cantoni²⁹ had shown to be an important methyl donor, could be increased and the biological transmethylation of amines facilitated. In some of the patients there was a temporary but quite obvious exacerbation of psychotic symptoms associated with methionine administration. These observations have now been confirmed by several other groups²⁹⁻³²; in addition, Brune and Himwich found similar effects with betaine, another methyl donor³⁰.

Further work by investigators in our laboratory has tended to support some of this reasoning. The absence of information regarding tissue levels of *S*-adenosylmethionine led Baldessarini and Kopin³³ to devise an ingenious assay of high specificity. By means of this they found a considerable elevation of *S*-adenosylmethionine in brain and liver of rats following methionine feeding. Axelrod³⁴ demonstrated the presence in normal mammalian tissue of an enzyme capable of methylating normal metabolites, that is, tryptamine and serotonin, to their dimethyl derivatives in the presence of *S*-adenosylmethionine. Dimethyltryptamine has been shown to be a potent psychotomimetic agent³⁵.

In 1962, Friedhoff and Van Winkle³⁶ detected a substance which behaved like 3,4-dimethoxyphenylethylamine in the urine of a substantial fraction of schizophrenic patients and which appeared to be absent from normal urine. That finding, which has had substantial confirmation by Bourdillon and Ridges³⁷, lends further support to the hypothesis of Osmond, Smythies and Harley-Mason, especially since it was that compound to which Harley-Mason had directed attention ten years previously.

Our observations of the effect of methionine in schizophrenic patients, as well as the findings of Friedhoff and Van Winkle, are open to a number of alternative explanations which have not been ruled out. Nevertheless, the hypothesis that the accumulation of one or more methylated compounds plays a significant part in some forms of schizophrenia remains a plausible and parsimoni-

Fig. 1. Present knowledge of the metabolism of epinephrine and norepinephrine (after Axelrod and Kopin)

ous explanation of a number of different and independent observations and seems worthy of further evaluation.

The possible interrelationships between the biogenic amines and affective states have become a subject of lively interest and productive investigations in the relatively few years which have elapsed since the pioneering studies of Gaddum and Vogt in Great Britain, Erspamer in Italy, Rapport and Woolley in the United States. Interest centred at first on serotonin after the remarkable demonstration by Shore *et al.*³⁸ of a depletion of that amine from the brain during reserpine-induced depression and its elevation following the antidepressant monoamine oxidase inhibitors. As evidence accumulated, however, it was learned that these drugs also affected noradrenaline- and dopamine-levels in the brain and that the catecholamine precursor, dopa, promptly and effectively reversed the depressant actions of reserpine in animals, suggesting to some an equally important role for catecholamines in the action of these drugs and possibly in affective states. It has been difficult to explain, however, the action of two effective antidepressant drugs in terms of the central biogenic amines. These agents, amphetamine and imipramine, are not especially active as monoamine oxidase inhibitors and have not been shown to elevate the levels of norepinephrine or serotonin in the brain.

Recently, Kopin was able to demonstrate, in the isolated, perfused heart, a differential metabolism of tritiated noradrenaline released under different circumstances³⁹. When the catecholamine was liberated in a manner which did not provoke its characteristic effects on the heart, that is, by reserpine, it appeared largely as deaminated products in the perfusate. On the other hand, when its release was accompanied by cardiac stimulation as with stimulation of the cardiac sympathetic nerves or by tyramine, *O*-methylated products appeared in the perfusate. These observations have suggested the generalization that catechol-*O*-methyl transferase is the enzyme normally involved in the degradation of norepinephrine which is released physiologically and perhaps its *O*-methylated metabolites are indicative of adrenergic activation, at least in the periphery.

The release and metabolism of noradrenaline in the brain, however, remained quite a mystery, since the blood-brain barrier prevented the uptake by the brain of radioactive norepinephrine and the amount of label which could be applied through synthesis from tagged tyrosine was hardly enough for fractionation. In 1964, Glowinski, who had applied Feldberg's technique to injection into the lateral ventricles of rats, joined Axelrod and Kopin and succeeded in developing what appears to be a valid technique for labelling, at a high specific activity, the norepinephrine stores within the brain by injecting the tritiated form intraventricularly⁴⁰. The label distributes itself quite rapidly in a pattern similar to that of endogenous norepinephrine and shows the same intracellular localization. Furthermore, it follows a curve of disappearance from the brain similar to that of ¹⁴C-norepinephrine endogenously produced from ¹⁴C-tyrosine.

With convincing evidence that they were studying the metabolism of endogenous norepinephrine in the brain, they examined the effects of a number of psychoactive drugs. Reserpine caused a rapid depletion and the predominant formation of deaminated products as it did in the heart. On the other hand, monoamine oxidase inhibitors, amphetamine and imipramine, all of which are antidepressant or euphoriant drugs, were followed by an increase in *O*-methylated norepinephrine products in the brain⁴¹. If one may generalize from Kopin's findings in the heart and infer physiological activity from an increase in norepinephrine *O*-methylation, these findings are compatible with the thesis that the drugs which induce depression or elevation of mood do so by depressing or facilitating the release of physiologically active nor-

epinephrine in the brain or altering its availability at effector sites.

Such a hypothesis as well as the possibility that normal and abnormal changes in mood are dependent on alterations of catecholamines in the brain remain to be validated. The possibility of labelling norepinephrine in the brain has overcome a major obstacle in the way of elucidating its physiological role there.

Another recent development in this laboratory has some clear-cut implications, this time for cardiology. Despite the expectation that monoamine oxidase inhibitors should elevate the levels of the sympathetic neurotransmitter, these agents are found to have hypotensive and other sympatholytic effects which, though undesirable in psychiatry, have been found useful in the treatment of hypertensive disease and angina pectoris. An explanation of this paradoxical effect has been advanced by Kopin *et al.*⁴², who presented evidence for the normal synthesis and accumulation of octopamine, the β -hydroxylated derivative of tyramine, in the region of the sympathetic nerve endings, its enhancement by monoamine oxidase inhibitors and its release by sympathetic stimulation. Their hypothesis that this relatively inactive amine may replace norepinephrine and act as a false neurochemical transmitter appears capable of explaining the partial sympathetic blockade observed after chronic inhibition of monoamine oxidase.

Much of what I have outlined is illustrative of an important generalization from the history of science, a principle which, though taken for granted by most scientists, nevertheless requires reinforcement to-day. The most practical way to attack a major medical problem or to bridge a great hiatus is not usually head-on, but by strengthening and extending the foundations on both sides and narrowing the gap which lies between. This is best accomplished when the scientists themselves choose their logical next steps, which each will do from his knowledge of the state of the field, the feasibility of an approach, the likelihood and significance of its being successful.

Nearly a hundred years ago in England, Thudichum, whom many regard as the father of modern neurochemistry, advanced a hypothesis that many forms of insanity were the result of toxic substances produced within the brain by faulty metabolism. But, more important, he went on to suggest that these processes, then quite obscure, would be obvious when we understood the biochemistry of the brain to its utmost detail⁴³. It was in the latter area that he spent the next ten years in what was to become the classical isolation, description and characterization of the chemical constituents of the brain.

It is not difficult to predict what would have resulted had Thudichum spent those years and the funds made available to him by the Privy Council in a premature search for the toxins of insanity. With the tools, techniques and knowledge available to him at that time, it is extremely unlikely that he would have found any of those hypothetical substances; it is equally unlikely that he would have made his fundamental contributions to our present knowledge of the biochemistry of the brain.

CHEMICAL EDUCATION

THE Royal Institute of Chemistry is launching an appeal for £100,000 with which to develop and extend its work in the educational field over the next five years. Already the Institute is spending £10,000 a year out of its limited resources on this work, but it is considered that a greatly increased effort is now urgently necessary if the Institute is to meet its national obligations to ensure an adequate supply of properly trained entrants to the profession.

With the present trend away from science in the schools and the consequent large number of vacant places in university science departments, the main emphasis for utilizing increased funds is placed on improving the teaching of chemistry at school-level. This, it is believed, is where the root of the problem lies, for only by presenting chemistry in a sufficiently attractive way to encourage boys and girls to adopt it as a career can the problems of the universities and the British chemical industry be solved. In fact, the marked decline in interest in chemistry on the part of school-leavers may be associated with lack of stimulation during their formative years at school, often due to out-dated methods of presenting the subject.

The trend away from chemistry in the school is disturbing in itself, but it is made more serious by the continuing shortage of qualified chemists in industry and elsewhere. It has been estimated by the secretary of one of the major university appointments boards that by 1970 there will be a shortage of some 10,000 qualified chemists in industry alone. This estimate is based on the best available figures, including those from the 1962 *Report of the Scientific Manpower Committee* and the 1961 *Census*. A particularly disturbing feature is that, on average, only 41 per cent of university graduates in chemistry enter industry—either directly or after staying at university for a higher degree. Indeed, in 1963 only 32 per cent of such graduates entered industry.

Present educational work of the Institute. The interest that the Institute now takes in educational matters stems from its functions as a qualifying and examining body, and in 1957 a Fund for the Development of Education in Chemistry was established to finance educational activities. With the exception of a repayable grant of £10,000 generously provided by the Nuffield Foundation for the launching of *Education in Chemistry* the Fund has been financed solely by the Institute, essentially out of its subscription income.

In addition to the new journal, *Education in Chemistry*, which was launched in 1964 and is now issued six times a year, the Institute, through its Trust Fund, publishes a series of *Monographs for Teachers* on aspects of chemical principles and arranges a number of symposia, or refresher

courses for teachers, as well as summer schools in chemistry. More recently it has organized, jointly with the Chemical Society, the first two of a series of review symposia for practising chemists.

Proposed future programme. The main emphasis of the Institute's five-year programme of work is on the teaching of chemistry in schools, because it is at this level that the need is greatest and also because experience over the past four or five years has demonstrated the ability of the Institute to help substantially in this sector. Moreover, the impetus given by the Nuffield Foundation to curriculum reform in science education provides a valuable opportunity for professional institutions to play their part in supporting complementary projects for the mutual benefit of the profession and the schools.

Among the projects to be sponsored for school teachers are: (a) Refresher courses; a flexible series of one-day symposia and one-week courses aimed at all teachers of chemistry (not just the keener ones) and also provision for married women wishing to return to the profession. (b) Bursaries; to enable a selected number of teachers to be seconded to a university or college of education, for a period of up to one year, in order to study modern aspects of chemical education and to take part in research projects in the field of science education. (c) Teaching aids; a series of teaching charts, filmstrips and other visual aids. (d) Surveys; to follow the progress of the projects outlined earlier and to use the information to modify the programme accordingly.

In addition to the problems of the schools there are very real difficulties to be tackled in the re-education of practising chemists and in the teaching of chemistry at university-level. The Institute intends to devote some of its funds to these problems.

Indeed, the importance of providing extensive courses, of short and long duration, for bringing practising chemists up to date in their subject and its applications cannot be over-emphasized. The expansion of scientific knowledge may mean that within fifteen years of graduation a scientist is ignorant of half the total knowledge in his field. This has given rise to a great deal of waste of older men and women and the 'too-old-at-forty' prejudice is re-establishing itself in British industry, at least for new appointments. The younger scientists are less out of date than their senior colleagues and the solution of retiring men early and replacing them by scientists under thirty is one that an increasing number of companies are using. That such a solution is unjust, wasteful and unsatisfactory goes without saying, and it may well defeat its own object by discouraging sixth-form pupils from choosing science as a career.

To combat this situation, a systematic and massive programme of refresher courses is required. Such a programme could be provided in the long vacations at selected universities and technical colleges and, because of its close liaison with these academic institutions and with industry, the Institute would be well placed to administer it for chemists.

Finally, the Institute proposes to devote a proportion of its funds to assisting the teaching of chemistry in the developing countries, especially the newly independent countries of the British Commonwealth. Help that might be given includes the provision of symposia and refresher courses for teachers, the secondment of teachers from the

United Kingdom, and the provision of all kinds of visual aids and of programmed learning techniques.

By acting as a pioneer and 'pump-primer' in the ways suggested in this article, the Institute feels that it can best exercise its function as an independent professional body in promoting the development of chemical education and ensuring an adequate supply of properly trained chemists to meet national needs in the United Kingdom and in the developing countries of the Commonwealth.

Further details about the proposals are contained in an appeal booklet available from the Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

OBITUARIES

Sir Ronald Hatton, C.B.E., F.R.S.

SIR RONALD HATTON died on November 11, 1965, in his eightieth year at his home in Benenden, Kent.

On leaving Balliol College, Oxford, he went to the South Eastern Agricultural College, Wye, Kent, and soon afterwards became a member of the horticultural staff there. Later he was transferred to the newly established Wye College Experimental Station at East Malling, where he assisted Wellington, the first director. After the First World War, Hatton was appointed director and remained so until his retirement in 1949. Under his guidance, despite numerous financial difficulties, the Station rapidly developed and attained a world-wide reputation. During the formative period he was whole-heartedly supported by the fruit industry of the United Kingdom and a devoted staff. When he retired he had the satisfaction of knowing that horticultural science was fully recognized as an essential service to the fruit-growing industry.

Hatton's own research in the 'twenties on rootstocks was a major turning-point in fruit culture. There were then wide variations within the same orchard in tree size and fruit quality: Hatton aimed at obtaining uniformity in both, and his research resulted in a series of rootstocks which imparted to the scion standardized growth characteristics. This was a major, if not the major, development for fruit culture throughout the world. Order was created out of chaos, for his work made possible a planned pattern for orchards and prepared the way for future trends in orchard practice, including, in particular, extensive mechanization. As a result, orchards of the future will be planted for high yields at the lowest possible costs.

Although pomological research remained his great interest, Hatton was fully alive to the importance of developing at the Research Station ancillary subjects such as plant physiology, applied entomology, plant pathology and statistics.

His delightful and friendly personality inspired confidence and was a constant stimulus to everyone, both in the Station and outside. His staff were known as "Hatton's boys" and there was among them a wonderful productive team spirit. His appetite for work was enormous and he was never satisfied that enough progress had been made. Perhaps his only fault—a forgivable one—was that he failed to realize anyone grew older, and although he knew that progress must require additional staff, he dreaded the Station expanding beyond a scientific "family circle".

Among his many achievements was the major part he took in the establishment of the Imperial Bureau of Fruit Production at East Malling, of which he was consultant director. His interests went far beyond his own Station: he was generous-minded to all and he had innumerable fruit-grower friends, who took his advice because it was so forward-thinking and practical. Undoubtedly there was in him a most happy blending of science and horticultural technology, which plays such a big part in the

well-being of a crop research station. The fruit-growing industry will for ever owe a great debt of gratitude to Sir Ronald Hatton.

H. G. H. KEARNS

Prof. E. J. Dijksterhuis

IN 1924, Eduard Jan Dijksterhuis, an obscure mathematics teacher in the Tilburg secondary school, published a book, *Val en Worp*, sub-titled "Contribution to the History of Mechanics from Archimedes to Newton", which was actually a summary of all that history could tell on this subject at that time, written by somebody who was obviously a master in this art.

Although the history of mathematics had flourished in The Netherlands for many years around the monumental work of editing Christian Huygens's works and the discovery and publishing of Isaac Beekman's journal, Dijksterhuis as a historian was an autodidact. He had attended the secondary school in Tilburg, where his father was the principal. Then, in order to be admitted to a university, he prepared for the final examination of a grammar school; this he passed after one year, at the age of seventeen. Still considered by his parents to be too young to study at a university, he spent one more year at home, during which he immersed himself in the classics, with which he had fallen in love during the preparations for his examination. Nevertheless, at the University of Groningen he chose his older favourite, mathematics, as his major subject. In 1918 he gained a doctor's degree for a thesis on a geometrical subject. Meanwhile, he had already taught at a Groningen girls' school, but in 1919 he agreed to fill a vacancy at the Tilburg school where he had been a student. This commitment did not end until 1953, when he was appointed a professor extraordinary in the history of mathematics and exact sciences at the University of Utrecht; from 1954 he also held an equivalent post at the University of Leiden. From 1960 until his retirement in 1963 he was a professor ordinary at the University of Utrecht.

From his marriage in 1920 with Johanna K. E. Niemeyer until his departure to Utrecht in 1953 he lived in the lovely Brabant town of Oisterwijk. In this rustic climate he matured as a scholar, and he wrote the greater part of his work. But he did not lead a retired life. For many years he was a 'privaat-docent' at the Universities of Amsterdam and Leiden—an activity which was interrupted by the Second World War. He played a great part in commissions on the teaching of mathematics and mechanics, and from 1934 until 1958 was a member of the Government Education Council (Onderwijsraad). For nearly a quarter of a century he was an honorary secretary to the most outstanding Netherlands literary periodical, *De Gids*. But, first of all, he was admired as a lecturer because of his firm grasp of the subject and the easy command of the language in which he expressed his thoughts.

His *Val en Worp* was followed in 1929–30 by his commentary (in Dutch) on Euclid's *Elements*. His *Archimedes* was written before the War; its English translation appeared in 1956. In 1943 his *Simon Stevin* appeared, and in 1950 the best known of his works, *De Mechanisering van het Wereldbeeld*, was published; the latter has been translated into German and English. Besides these books, he published a large number of papers, lectures and addresses on historical, educational and philosophical subjects. His longest-lasting activity was that of chairman of the Royal Netherlands Academy Commission on the Edition of Works of Simon Stevin, which still met at his home when he had lost his speech and had to rely on gestures to conduct its meetings.

Educated people, and above all scholars of the humanities, were struck by his style. He abstained completely from metaphors, puns, oratorical and dramatic effects, and from any choice of words that would excite emotions rather than thoughts. He was a lover of art and poetry, but in his own work he never gave way to the spell of rhetoric. He put his thoughts into a form which matched their contents, and above all matched his character. He wished to grip the reader by the subject rather than by the form—though just for this reason it was the form which fascinated.

For his *De Mechanisering van het Wereldbeeld* he was awarded a high literary honour; he was a member of the Royal Netherlands Academy of Sciences, a bearer of the Karl Sudhoff Medal of the Deutsche Gesellschaft für Geschichte der Medizin, Naturwissenschaften und Technik, the George Sarton Medal of the American History of Science Society and many other honorary awards.

H. FREUDENTHAL

Prof. R. H. Hopkins

PROF. R. H. HOPKINS, who was formerly Adrian Brown professor of brewing and applied biochemistry in the University of Birmingham, died recently after a short illness at his home in Bournemouth, aged seventy-four.

His association with Birmingham was a long one, as he graduated in 1910, after which he gained experience in various analytical laboratories. He returned to the University towards the end of the First World War and became assistant to the first professor of brewing, Prof. Adrian Brown.

He became a Fellow of the Royal Institute of Chemistry in 1918, and served on the Council for two periods.

In 1920 he took up an appointment in the Department of Chemistry of the Heriot-Watt College, Edinburgh, and

was in charge of courses in malting and brewing and biochemistry. In 1926 he was awarded an M.Sc., and in 1928 a D.Sc. of Birmingham. When the Adrian Brown chair of malting and brewing fell vacant in Birmingham, his record and qualifications rendered him a very appropriate candidate, and he was appointed in 1931.

Hopkins always, and rightly, insisted that the biochemical principles on which the art of malting and brewing rested were of fundamental importance, and he strongly resisted attempts to isolate the School of Brewing. He was able to maintain the dual nature of the Department as a School of Brewing and Department of Industrial Fermentation, later of Applied Biochemistry. There is little doubt that without this steady pressure over the years there would have been no Department of Biochemistry as it exists to-day.

He was primarily a man of academic interests, but he combined this to a very unusual degree with a knowledge and appreciation of the technical processes and problems involved in malting and brewing. This is clearly demonstrated in the large number of papers which he contributed to the *Journal of the Institute of Brewing*, the *Biochemical Journal* and other journals of a more technical nature. There is scarcely any fundamental aspect of malting and brewing which he failed to deal with in his publications.

A topic which held his sustained interest over a number of years was the nature of starch and the complex amyolytic actions involved in its breakdown. He did much to bring order and clarity into a field of research where confusion reigned, and his claim to recognition will doubtless be confirmed in future perspective.

He directed a team of research workers in the Department under the aegis of the Institute of Brewing from 1934 until 1950, when it became absorbed in the Brewing Industry Research Foundation in Surrey. During the Second World War he sponsored work by the teaching staff on the qualitative and quantitative aspects of vitamins in beer. Most of the water-soluble vitamins came under scrutiny, and the large and useful amounts of riboflavin which occurred naturally in the beverage were reported for the first time.

He was a frequent participator in symposia and congresses throughout the Western world, and made several lecture tours of the United States.

His other interests included a deep appreciation of many branches of music, and he was particularly fond of holidays in the mountains and by the lakes of the Continent. He will be missed by a host of colleagues, students and friends.

F. W. NORRIS

NEWS and VIEWS

European-American Committee on Reactor Physics

DR. V. RAIEVSKI, head of the Reactor Physics Department at the Ispra Joint Nuclear Research Centre of Euratom, has been elected chairman of the European-American Committee on Reactor Physics for the next 2 years. Dr. Raievski succeeds Mr. Peter Mummery of the Atomic Energy Establishment, Winfrith, U.K. At the same time, Dr. H. Kouts, of Brookhaven National Laboratory, has been elected scientific secretary of the Committee in succession to Mr. E. Critoph of Atomic Energy of Canada, Ltd., Chalk River. The European-American Committee on Reactor Physics is a group of fifteen reactor physics experts from member countries of the Organization for Economic Co-operation and Development, and Euratom (nine from Western Europe, three from the United States, one each from Canada, Japan and Euratom). It was set up in 1962 by the Steering Committee of the European Nuclear Energy Agency,

which recently confirmed its mandate for a further 4-year period. The work of the Committee consists of reviews of national programmes in reactor physics, periodical examination of research on selected topics, and exchange of information on new research results. The Committee also advises on priorities for new research activities.

Analytical Chemistry in the National Bureau of Standards:

Dr. David H. Freeman

DR. DAVID H. FREEMAN recently joined the Analytical Chemistry Division of the Institute for Materials Research at the National Bureau of Standards. His work will be concerned with the prediction, control and reproducibility of analytical separations, and he will deal especially with the relationships between chemical specificity and the structure of ion-exchange derivatives of synthetic organic copolymers. Dr. Freeman was formerly an assistant professor at Washington State University, where his

research activities were supported by a contract from the Atomic Energy Commission. From 1958 until 1960 he worked as a research associate at the Massachusetts Institute of Technology. Born in Rochester, New York, Dr. Freeman completed his B.S. in chemistry at the University of Rochester in 1952; he then went to the Carnegie Institute of Technology for his M.S. in 1954, and gained his Ph.D. at the Massachusetts Institute of Technology in 1957. His professional affiliations include membership in Phi Lambda Upsilon (president of the Massachusetts Institute of Technology Chapter in 1958-1959), American Chemical Society, American Institute of Physics, American Optical Society, American Association for the Advancement of Science, and Sigma Xi.

Preserving the Lake District

SOME of the points raised in the *Report and Newsletter*, September 1965, of the Friends of the Lake District are noted elsewhere in discussing the "Countryside in 1970" Conference (see pp. 1241, 1265 of this issue of *Nature*). It is obvious from the report, however, that the Friends of the Lake District are concerned that considerations of amenity are being pushed into a minor place in proposed amendments to the National Parks Act. They feel that without the expression of a widely based and well-informed body of public opinion the objects for which National Parks were created are unlikely to be achieved. Much of the criticism in this report centres on the water plans of Manchester, particularly the powers sought to construct a duplicate in Longsleddale of the Mardale tunnel, although it is recognized that the Order has been most carefully framed and that the initial quantities of water to be abstracted are so calculated that it is extremely difficult to estimate the effect on the two lakes. It is the ultimate effects and the immediate physical effects on Longsleddale that are the cause of misgivings, and the report does well to emphasize the viable alternative of extraction from rivers rather than lakes, and of the possibilities of desalination: consideration of our water resources in terms of nineteenth-century thought is no longer valid. One welcome feature of the report is an indication of some improvement in the litter position, although constant effort and vigilance are still necessary.

Information Activities of the U.S. National Academy of Sciences

THE scientific information activities of the National Academy of Sciences—National Research Council of the United States are surveyed in a booklet recently issued by the Office of Documentation (National Academy of Sciences—National Research Council. Publication 1291: *Scientific Information Activities of the National Academy of Sciences—National Research Council*. A Report of the Office of Documentation. Revised 1965. Pp. 116. Washington, D.C.: National Academy of Sciences—National Research Council, 1965). This is a revision of a booklet issued under the same title in 1962. It covers such activities as the preparation of abstracting periodicals and literature digests, bibliographies, codes and classifications, tables of data, glossaries, handbooks, indexes, lists of publications, reviews, translations, the maintenance of information centres and the provision of information services, as well as studies and analyses in these fields. Original research publications are not included unless concerned with these fields. The information is arranged alphabetically by the several divisions of: behavioural sciences; biology and agriculture; chemistry and chemical technology; earth sciences; engineering and industrial research; mathematics; and physical sciences. Within these are given, alphabetically by title, details of the committees, boards, offices or similar units.

Scientists in the 'New Deal'

THE summer issue of *Minerva* contains an interesting article by L. E. Auerbach, "Scientists in the New Deal",

reviewing the relations between science and Government in the United States at the time of the formation of the Science Advisory Board. The article is essentially an account of the establishment and work of the Science Advisory Board under the National Research Council during its brief existence from July 1933 to December 1935. The Board sought to broaden the perspectives of the Government and to increase its awareness of foreign scientific achievements, but Mr. Auerbach considers that many of its recommendations were made largely in a political vacuum and that its attempt to formulate a comprehensive national science policy was essentially a failure, although the Board itself was rather a failure in adaptation to a new situation. This is attributed largely to conflict between the National Academy of Sciences and the Science Advisory Board. Dr. K. T. Compton held that if the National Academy of Sciences had been more involved with the social sciences, many of the difficulties would have been avoided. Mr. Auerbach also suggests that the Board would have been more influential if the scientific community as a whole had been able to agree on a united stand on the need for a national science policy. To-day its most valuable contribution to national welfare and towards raising the support and status of basic research appears to be the political experience it gave to men like K. T. Compton, I. Bowman and Vannevar Bush.

Science and Economic Growth

AN article by Dr. C. E. Chastain, "Science, Technology and Economic Growth", in *Impact of Science on Society* (14, No. 4; 1964) reviews some recent studies of the relation of science and technology to economic growth and emphasizes the need for further understanding of those relations, which require studying at three levels. We need to know more about the diffusion of technological knowledge for the development of new products and processes at the level of the individual firms in an industry. We need, next, a detailed study of some major industries, emphasizing the capacity of firms to adopt new technologies and analysing what motivates or hinders their advance. Thirdly, studies of the effect of technological change on the overall economy would also illustrate how technological change promotes new industries and new sectors in the economy. The Industrial Development Research Programme of the Institute of Science and Technology at the University of Michigan has recently completed an investigation, at the firm level, of engineering and technical developments and their business implications in the Michigan machine-tool industry, and a similar investigation of the electronics industry will shortly be completed.

The Royal Society of Edinburgh

THE *Year Book of the Royal Society of Edinburgh, 1965*, covering the session 1963-64 (Pp. 133. Edinburgh: Royal Society of Edinburgh, 1965. 20s.; 3.50 dollars), contains the usual calendar, obituary notices, proceedings of the ordinary meetings and of the statutory general meeting, together with laws of the Society, accounts for the year ended July 21, 1964, and lists of Fellows of the Society, members of Council and recent awards. There are also lists of additions to the Library and of papers recently published in the *Proceedings* and *Transactions* of the Society. Among the obituary notices are those of W. M. Ames, Prof. R. N. Arnold, L. E. Bayliss, Prof. E. Finlay-Freundlich, A. H. R. Goldie, Prof. I. A. Preece and Sir James Wallace Peck.

The Manchester Literary and Philosophical Society

THE *Memoirs and Proceedings of the Manchester Literary and Philosophical Society* (107; 1964-65. Pp. 142+lii. Manchester: Manchester Literary and Philosophical Society, 1965. 31s. 6d.) includes, besides the account report of the Council, accounts, lists of presidents of the Society,

Council members, awards of the Dalton Medal and special lectures, Sir William Slater's Joule Memorial Lecture, "The State as the Patron of Science". Other papers in the *Memoirs* include those by K. F. Bowden on progress in oceanography; N. L. Hanson on "The Architect's Dilemma"; G. Polanyi on "North Sea Gas—What will it Mean?"; F. Oldfield and D. C. Statham on "Stratigraphy and Pollen Analysis on Cockerham and Pilling Mosses, North Lancashire"; R. H. Kantorowich on "Choice and Chance—Prospects for the North-West"; Brian Rodgers on "Making Social Policy"; and an autobiographical sketch of J. B. Dancer, with a foreword by W. Browning.

National Art Gallery and Dominion Museum, New Zealand

THE year 1965 marks the centennial year of the Dominion Museum and is being celebrated by evening functions, special exhibitions and the publication of a history of the Museum. In addition to various curatorial activities, the extra-mural influence of the institution is particularly impressive and includes circulation of works of art and museum specimens, public lectures, scientific excursions and advice on conservation. Exhibition effort has been concentrated mainly in the Maori Hall, new cases of foreign aviary birds, early silver, and the completion of a reconstruction of an Egyptian tomb (a life-sized X-ray negative of the mummy was added to this exhibit). The report for the year ended March 31, 1965, also records the opening of the Hall of Memories in 1964 and comments on the beauty and artistry of the interior and the manner in which the symbolic message is conveyed (New Zealand. Report of the Board of Trustees of the National Art Gallery and Dominion Museum for the year ended 31 March, 1965. Pp. 28. (H.21.) Wellington: Government Printer, 1965. 1s. 6d.).

French Oceanography

THE September 1965 issue of *Le Progrès Scientifique* (No. 88) is devoted to a survey of the situation and perspectives of French oceanography, with, for comparison, an estimate of expenditure on oceanography in Great Britain and in the United States programme for 1966. Some 596 scientists and engineers are estimated to have been engaged on oceanographic research in France in 1964, equivalent to 450 full-time workers; the corresponding expenditure is estimated at 90–100 million francs. There is also a brief account of three recent French contributions to the advance of oceanographic technique in the Bouée laboratory, the submarine seismograph, and the Télénaut.

Chemical Analyses of Rocks and Minerals

THE latest of a recent succession of regional compilations of chemical analyses of rocks and minerals, prepared to facilitate the more ready use of data in the files of Government departments, emanates from the Geological Survey of Canada and is the first part of a project designed to bring together all available Canadian geochemical information (Canada: Department of Mines and Technical Surveys. *Geological Survey of Canada. Bulletin 115: Chemical Analyses of Canadian Rocks, Minerals, and Ores*. By J. A. Maxwell and others. Pp. 476. Ottawa: Queen's Printer, 1965. 6.50 dollars). It comprises analyses, with petrographical and topographical annotations, made by the Survey from the time of its foundation in 1846 up to the end of 1955. This follows closely on a similar monograph based on sixty years of records of the Geological Survey of Malaya (*Geological Survey of Malaya Professional Paper E-64: Chemical Analyses of Malayan Rocks, Commercial Ores and Mineral Concentrates*. Compiled by J. B. Alexander and others. Pp. 295. Ipoh: Malaysian Ministry of Lands and Mines, 1964. 10.00 Malayan dollars). In the U.S.S.R., an important regionally based collection of

some 2,000 full (but not annotated) chemical analyses of rocks and rock-forming minerals, mostly executed in recent years, has appeared under the aegis of the Institute for Ore-Deposit Geology, Petrography, Mineralogy and Geochemistry (*Khimicheskie analizy izverzhennykh gornykh porod i porodoobrazuyushchikh mineralov*. Compiled by V. F. Morkovkina. Pp. 250. Nauka, Moscow, 1964. 3r. 66k). It carries useful calculations of the average composition of the more important rock-types in the several regions of the U.S.S.R. A fourth recent work of this kind is a compilation by Miss Germaine A. Joplin of the analyses in Australian literature (*Chemical Analyses of Australian Rocks*. Part 1: *Igneous and Metamorphic. Bureau of Mineral Resources, Geology and Geophysics Bulletin, 65*. Pp. 4+6. 1963). Part 2 of the Australian monograph, on sedimentary rocks, is in preparation. These several works bring together data from a wide range of sources and they will save petrologists much tedious searching of the literature.

Chiswick–Langley Section of the M.4 Motorway

THE Chiswick–Langley section of the M.4 motorway opened by Mr. T. Fraser, the Minister of Transport, on March 24, 1965, is 12.5 miles long, and contains the longest stretch of elevated road in Europe; incidentally, it also incorporates a much-needed link road to London Airport. Some interesting details of the design and construction of this highway, with its viaducts, overbridges, underbridges and footbridges, some of which are illustrated, are contained in an article, "Chiswick–Langley Section of the M.4" (*Concrete Quarterly*, No. 65; April–June, 1965. Cement and Concrete Association, London). For about the first 2 miles from the Chiswick end, this motorway is a viaduct with two twin-lane carriageways. The first mile or so is constructed with pre-cast, pre-stressed concrete deck beams carried on T-shaped piers; this follows the line of the Great West Road. The remainder of the viaduct swings away from the Great West Road and is of steel and concrete construction. There are thirty-one bridges between Chiswick and Langley, including the link road to London Airport; these owe their lightness of form and speed of construction to the use of pre-cast concrete units and pre-stressing techniques. Twelve bridges carry roads over this new section of the M.4; sixteen carry the motorway itself over roads, railways, canals and rivers; three footbridges are available for pedestrians, and sixteen pedestrian subways have been constructed at various points along it. At the end of the elevated section, where it descends to ground-level, the carriageways widen to accommodate three 12-ft. lanes; outside these carriageways are constructed hard shoulders, 10 ft. wide, bounded by grass verges of similar width. The length of approximately 7 miles between Boston Manor and London Airport is in concrete; between the Airport and Langley interchanges there are approximately 4 miles of flexible construction on various bases; this section was purposely laid for practical specification trials by the Road Research Laboratory. It is stated that the concrete road slab is 38 ft. wide, 11 in. thick, with welded steel mesh reinforcement 3 in. below the top surface. The consolidated granular sub-base is between 7 in. and 12 in. thick. Expansion joints are provided every 240 ft. and contraction joints at 80-ft. centres. The illustrations in this article, including one of the elevated section of the motorway with slip roads at the Brentford interchange, and one of an elegant pre-stressed footbridge with spiral ramp at the Langley interchange, are particularly good.

Shrinking Aggregates a Cause of Failure in Concrete

THERE exists an extensive literature on research into failure of concrete ascribed to instability of aggregates involved, both physical and mineralogical. Aggregates known to exhibit excessive dimensional change on drying out and ageing of concrete would normally be inad-

missible, but there are cases on record where such materials have been used, apparently with disastrous results. Thus there is every reason for investigating those rocks which are potentially vulnerable to dimensional instability when emplaced as aggregates in concrete, and especially the role of the mechanism set up by shrinkage in causing distress and ultimate breakdown. This problem has recently been successfully tackled by H. Roper, J. E. Cox and B. Erlin, in a joint paper entitled "Petrographic Studies on Concrete Containing Shrinking Aggregate" (*Journal of the P.C.A. Research and Development Laboratories*, 6, No. 3; September 1964. Pp. 2-18. Portland Cement Association Research and Development Laboratories, Skokie, Illinois). As the title implies, the approach to the problem of shrinkage of aggregates is essentially petrographic; it has been shown that this technique is useful in detecting and diagnosing distress in concrete, also in supplying new information leading to a more complete understanding of the phenomena involved.

Two extreme cases of aggregates known to possess high-shrinkage properties resulting from water loss were chosen for this investigation, both from Karroo System of South Africa. These materials were used because their physical properties have been thoroughly studied; they were used in a distressed building, which initiated investigations on excessive dimensional instability, and it was considered important to use materials which had given rise to the largest shrinkages recorded. The material used as coarse aggregate was the Adendorp Sandstone, from a quarry in Cape Province, Union of South Africa, with a water absorption of 5.78 per cent; the fine aggregate was Kruidfontein Sand, with a water absorption of 4.17 per cent. Petrological studies of concretes made from these aggregates show that internal cracking of the mass has resulted from shrinkage of the aggregate; cracking occurs around aggregate particles and is sometimes modified by the relative positions of adjacent particles. The various stages of cracking and disruption of concrete due to this mechanism are convincingly illustrated in this paper in a series of ground sections of specimens examined, accompanied by interpretative diagrams showing the precise relationships between peripheral, to a lesser extent radial, crack developments and the aggregate particles causing the trouble. An important general observation is made in this paper; it appears from the examination of many concrete aggregates that rocks prone to excessive shrinkage when used for this purpose often contain clay minerals, which may occur as matrix materials, as alteration products of minerals due to weathering, or to the formation of secondary unstable minerals under hydrothermal conditions (for example, chlorophaeite in the case of some basic igneous rocks).

Reactivation of the Hijaz Railway, Saudi Arabia

ONE of the world's most famous railways, the Hijaz Railway, linking Esh Sham (Damascus) in Syria, Amman in Jordan, and Medina in Saudi Arabia, and its contemporary reactivation, is the subject of an interesting and well-illustrated article by Daniel da Cruz, entitled appropriately "Pilgrim's Road", and published in a special issue of *Aramco World* (16, No. 5; September-October, 1965. Arabian American Oil Company, New York, 10022). This was originally an Ottoman Empire project designed to link Damascus with Medina and Mecca, and destined to follow the centuries-old pilgrims' route through the then forbidding country of Hijaz, bordering the Red Sea. Construction of the Hijaz Railway commenced in May 1900; by September 1901 the first section, Damascus-Der'a, was completed; a year later the Der'a-Zarqua section was opened, to be followed by the extension to Amman in 1903, thence to Ma'an in 1904, Tabuk in 1906, Mada'in Salih in 1907, reaching Medina in 1908. For various political reasons it was not prolonged to Mecca. Thus, in the course of eight years the Turks

had put down 808 miles of rail, a remarkable engineering feat considering the nature of the country, the climate, and the attitude of often hostile inhabitants. But the aspirations of the promoters of this worthy project were doomed, largely because of the advent of the First World War when Turkey sided with the Central Powers and her occupation of the Middle East threatened the Suez Canal, along which passed the vital lifeline between Britain and her maritime bases in the Far East. Following the Allied capture of Aqaba, many Turkish locomotives and many miles of track were destroyed; travelling on this railway became an uncertain adventure; civilian traffic languished, and with the termination of hostilities, ceased altogether. After 1918 the Allies set about repairing as much of the line as possible; so much so that despite many vicissitudes, a fairly regular service on the Damascus-Ma'an section has been maintained up to the present day. But rehabilitation of this famous railroad was inevitable, especially on the long-abandoned Ma'an-Medina section. Following the independence of Syria and Jordan, an Executive Committee for Recommissioning the Hijaz Railroad Line was established, representing Syria, Jordan and Saudi Arabia; a re-survey was undertaken in 1956, culminating with a contract being placed for the necessary reconstruction in 1963. Work began in March 1964, and if the projected schedule is met, there is every reason to anticipate this reactivation towards the end of 1966. Apart from the details of this Hijaz Railway scheme, this number of *Aramco World*, entirely devoted to Saudi Arabia, contains other articles, and a remarkably fine series of coloured and black-and-white photographic illustrations which bring to life glimpses of "Arabia the Beautiful", as it is herein described, but equally leave little to the imagination of what the founding and now the revitalizing of the Hijaz Railway have really meant in terms of human effort and achievement.

National Institute of Agricultural Engineering: Component Failure Investigation

A 'COMPONENT failure investigation' service has been started at the National Institute of Agriculture to enable a manufacturer who is investigating the cause of failure of a component in an agricultural machine to draw on experience accumulated in the course of machinery testing and research and on the facilities available at the Institute. The work done by the Institute, which is on a confidential basis, can include laboratory examinations, calculations and possible rig testing, but any extensive field tests or collection of information about machines in service will normally be carried out by the manufacturer. A consultation fee of from £5 to £20 will be charged for the initial examination, which will be based on written evidence and samples supplied by the manufacturer. If further work is needed, a programme and cost estimate will be agreed between the manufacturer and the Institute, and the closest possible liaison will be maintained throughout the work. The new service, which has been welcomed by the Agricultural Engineers' Association, will be operated by the Materials Engineering Section of the Engineering Division, National Institute of Agricultural Engineering, Silsoe, Bedfordshire, from which further details can be obtained.

Pollen Studies in New York State

AN ambitious and well-planned attempt to reconstruct the vegetational and climatic events from late glacial into post-glacial and recent times is recorded in Bulletin 397 of the New York State Museum and Science Service (*Pollen Studies in the Cruso Lake Area of Prehistoric Indian Occupation*. Donald D. Cox and Donald M. Lewis. Pp. iii + 29. Albany, New York: The University of the State of New York—The State Education Departments, 1965). Prehistoric Indian sites are widely distributed in the immediate area, and the authors have also tried to incorporate this occupational evidence into the climatic

sequence, although their success in this aspect is rather limited, because no indications of cultivated plants were found in any of the pollen profiles taken from three different areas. Of some interest is the tentative recognition of three episodes within late glacial times, representing the pre-Valders ice retreat, Two Creeks interstadial and Valders ice advance, although until now it was believed that the Valders re-advance in fact covered the area. The detailed geological evidence for this is not discussed, but clearly some further consideration is required to resolve the problem. The subsequent post-glacial vegetational history is well documented, and radiocarbon dates from the area and elsewhere combine to present a closely detailed picture of the environmental conditions which influenced the prehistoric Indian groups attested here from about 3000 B.C.

Traditional Celtic Customs

THE latest issue of *Folk Life* (3; 1965), the journal of the Society for Folk Life Studies, contains a number of papers recording traditional customs and technological processes of certain areas within the British Isles. It is noteworthy that almost all the areas selected for study are in the 'Highland Zone', the Celtic fringe of north-western Europe. A well-illustrated article on "Pennine Houses" records a number of constructional features ranging from cruck-framed houses and fourteenth-century aisled halls to stone buildings of the eighteenth century. There follow papers dealing with Cornish migrants to America, customs and traditions in Glamorgan and Ulster, and elver fishing on the Severn. Of particular interest is the publication of a plan, with descriptive text, of the multiple-tenancy farm at Auchindrain in mid-Argyll. The fine preservation of this complex is due to a continuity of occupation down to relatively recent years, and the linear settlement, of mainly cruck-framed buildings, is expected to be maintained in its present or restored state. Of more widespread interest may be the paper on holed stone amulets and their traditional use as protective or recuperative agencies against such misfortunes as nightmare, bewitching and disease of horses and cattle, rheumatism, and night-riding. The volume also contains a number of notes and reviews.

Commentariolus of Copernicus

Dr. J. Dobrzycki (Institute for the History of Science, Polish Academy of Science, Warsaw) and Dr. W. P. D. Wightman (Department of History and Philosophy of Science, King's College, Aberdeen) have written to the Editor as follows: "It is fairly generally known that early in his life, and some considerable time before the publication of his epoch-making *De Revolutionibus*, Copernicus circulated a few MS. copies of a brief work (commonly referred to as the *Commentariolus*) in which the idea of a heliocentric system was sketched out. Before the end of the sixteenth century Tycho Brahe had difficulty in obtaining a copy; thereafter it disappeared until the nineteenth century when two copies—an apparently complete one in Stockholm, and a somewhat defective one in Vienna—were brought to light. A few years ago a single page of the *Commentariolus* was discovered in the interleaved copy of the Basle (1566) edition of the *De Revolutionibus* in the hand of Dr. Duncan Liddel (whose library passed to the Marischal College and University of Aberdeen on his death in 1613) (*Science and the Renaissance*, 2, item No. 172; Edinburgh, 1962). A further search recently gave promise of a complete transcript of the *Commentariolus* on inserted folios widely scattered throughout the book. As a result of a more detailed collation we are now convinced that these MS. pages comprise a complete transcript corresponding closely to, but differing in some significant features from, the Stockholm MS. of the *Commentariolus*. A new revision of the *Commentariolus* based on all extant transcripts will be prepared in the Institute for the History of Science

(Polish Academy of Science) in Warsaw with the view of publication, probably in the course of 1966".

Albert Lasker Medical Research Awards

THE twentieth annual Albert Lasker Medical Research Awards have been presented to Prof. A. B. Sabin, professor of research pediatrics at the University of Cincinnati College of Medicine, in recognition of his fundamental contribution to the understanding of the nature of poliomyelitis, and the development of a live vaccine that can be taken by mouth, and to Prof. R. W. Holley, professor of biochemistry at Cornell University, in recognition of his determination of the chemical structure of alanine tRNA.

Feldberg Foundation Award

THE British prize-winner for 1965 of the Feldberg Foundation Award is Prof. B. Katz, of the Department of Biophysics, University College, London, and the German prizewinner is Dr. G. Braunitzer of the Max-Planck-Institut für Biochemie, Munich. The Feldberg Foundation for German-English scientific exchange was established in 1961 through the generosity of Prof. W. Feldberg, a member of the staff of the Medical Research Council at the National Institute for Medical Research, London. The Foundation provides for a prize to be awarded each year to one German and one British scientist. In recognition of the gift the German recipient gives a lecture in Britain and the British prizewinner lectures in Germany.

Davissson-Germer Prize

THE American Physical Society and Bell Telephone Laboratories have announced the establishment of a new Prize for outstanding contributions in the fields of electron and atomic physics. The award will be given in honour of the late C. J. Davissson and of L. H. Germer, former members of the research staff of the Bell Laboratories, and pioneers in the study of the wave-like quality of electrons. The award will be presented every other year by the American Physical Society until 1973, and will consist of a 2,500 dollar cash prize and a citation describing the accomplishments of the recipient.

New Shell Research Fellowship

A NEW series of post-doctoral research fellowships, each worth £1,300 per annum, has been instituted by Shell International Petroleum Co. in extension of the considerable support it already gives to research and education. This is announced in the November issue of Shell's *Science and Technology Newsletter*. These awards, tenable for 2 or 3 years in any university, college of technology or other recognized research establishment in Britain, are intended to assist Fellows to pursue research on a subject of their own choice lying within the spheres of engineering, mathematics, physics, chemistry, biochemistry, botany, zoology or microbiology—disciplines with which Shell's own research in the United Kingdom is concerned. Two awards will be made each year. Candidates may be of any nationality but must hold a Ph.D. degree or equivalent, and be less than thirty years old on October 1 of the year of appointment. Application forms for the 1966-67 research fellowships can be obtained from the Secretary, Shell Grants Committee, Shell Centre, London, S.E.1, and should be returned by February 1, 1966.

South-East Asia Treaty Organization: Research Fellowships

THE British Council, on behalf of the South-East Asia Treaty Organization (SEATO), announces that SEATO research fellowships for 1966-67 are available to scholars whose academic standards are of approximately doctorate level. The research projects for which the SEATO grants will be given should relate to social, economic, political,

Science Reporter, published by the Council of Scientific and Industrial Research, New Delhi, has published a "Haldane Number" (2, No. 11; November 1965. 50 p.). This is devoted entirely to assessments of the late Prof. J. B. S. Haldane by numerous European and Indian scientists. As might be expected, it deals more fully with the Indian period of his life, but other aspects are not neglected.

Announcements

MR. E. B. TEESDALE has been appointed director of the Association of the British Pharmaceutical Industry as from December 1.

Dr. A. R. COLLIES has been appointed director of the Civil Engineering Research Association as from January 1, following the resignation of Dr. M. F. Kaplan, who has been appointed professor of civil engineering at the University of Cape Town.

DR. B. R. NIJHAWAN, director of the National Metallurgical Laboratory, India, has been awarded the 1964 Shanti Swarup Bhatnagar Memorial Award for his contributions in the field of engineering sciences by the governing body of the Indian Council of Scientific and Industrial Research.

DR. F. AYLWARD has been appointed director and Dr. T. G. Gillespy deputy director of the Fruit and Vegetable Canning and Quick Freezing Research Association.

The seventh international Transplantation Conference, sponsored by the New York Academy of Sciences, will be held in New York City during February 14-16. Further information can be obtained from Felix T. Rapaport, New York University Medical Center, 560 First Avenue, New York 16, N.Y.

A SEMINAR on "The Role of a Ministry of Technology", arranged by the Science of Science Foundation, will be held at the Ciba Foundation, London, on February 21. Further information can be obtained from the Science of Science Foundation, c/o the Ciba Foundation, 41 Portland Place, London, W.1.

A MEETING of the Midlands Section of the Society for Analytical Chemistry will be held in the University of Birmingham on January 5. During the meeting the Elwell Award will be presented. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

CORRIGENDUM. In the article entitled "Transpiration as related to Internal Water Content", by Dr. E. R. C. Reynolds, which appeared on p. 1001 of the August 28, 1965, issue of *Nature*, the quantities of water, where expressed as equivalent depths of water, are 6.1 times too large.

ERRATUM. In the article entitled "Relationships between Constituents of Cones and Male Flowers of the Hop (*Humulus lupulus*, L.)", by Dr. R. D. Hartley and Dr. R. A. Neve, which appeared on p. 804 of the November 20, 1965, issue of *Nature*, the seventh word on the second line should read 'brewing', not 'breeding'.

THE COUNTRYSIDE IN 1970

By E. M. NICHOLSON, C.B.

Director-General, The Nature Conservancy, 19 Belgrave Square, London, S.W.1

CONFERENCES nowadays follow one another so rapidly that those most involved in them may find it hardest to assess their real objectives in relation to what they actually do and what, if any, further results flow from them. Yet the fact that conferences monopolize so much time of busy people and cost so much to organize and attend casts a moral obligation on their promoters not only to see that these resources are well spent, but also to provide their quota towards the necessary data for developing the science and art of holding conferences, as well as towards whatever may be the subject-matter of their own exercise. This is borne in mind in the following discussion of the Duke of Edinburgh's Second Study Conference on "The Countryside in 1970", held in London during November 10-12, 1965.

Conflicts between developers accused of despoiling the countryside and champions of its preservation go back at least to Wordsworth, and arguably to John Evelyn, who succeeded three centuries ago in promoting what would now be termed a highly successful conservation campaign against the ironmasters who were laying waste the English woodlands. Thus vanquished, they found necessity the mother of invention to the extent of devising means of substituting coal for charcoal and thus, under conservationist pressure, finding the way to creating the steel industry. During the nineteenth century, however, development in its crudest forms was increasingly permitted, and the well-meaning voluntary bodies formed to combat such tendencies never won enough support or attained enough cohesion to reverse the trend. This was dramatically shown in the main London exhibition for National Nature Week in 1963. Following a visit to the exhibition the Duke of Edinburgh resolved to bring the parties together at a study conference in the autumn of 1963 to seek a means of agreeing on both a diagnosis and an approach to a remedy before, as he feared, the national inheritance in the countryside became irrevocably damaged by about 1970.

Hurriedly improvised and patchily documented, the 1963 Conference was nevertheless judged a considerable success. It brought together representatives, mainly at a high level, of some ninety national organizations including Government departments and public concerns, professions, scientific and technical organizations, and bodies representative of industry, agriculture, landowning, recreation, natural history, amenity and other interests concerned.

Many of these were hitherto scarcely aware of the existence of one another, and it proved a revelation for them to meet face to face in the three large working parties and to begin to learn of their respective aims, problems, policies and points of view. By the time the Conference ended, it had initiated many fruitful contacts, harnessed much vague goodwill into a definite, if frankly empirical, common movement embracing hitherto conflicting parties, and prepared the way for a more scientific and educational treatment of the whole vast complex of problems.

Such treatment was facilitated by a contribution from the Nature Conservancy of a chart of "Human Impacts on the Countryside", prepared by A. W. Colling and myself. This chart listed and analysed the incidence and effects of all traceable activities and operations (numbering more than 160) involving distinguishable types of impact by a human group or organization on the country-

side. The Conference directed much attention to requirements in terms of research and investigation leading to a better understanding of the problems. Following publication of the *Proceedings* of the Study Conference (H.M.S.O., 1964), an exhaustive analysis was made of all the suggestions, and recommendations for action or for further study. Three follow-up conferences were arranged, on "Agricultural Chemicals—Progress in Safe Use" held in London in March 1964, and on Scottish aspects held at Inverness in April 1964, and on educational aspects at the University of Keele in March 1965. Special account was also taken of a number of allied projects, including the National Trust's "Enterprise Neptune" for saving key areas of coastline, the Nature Conservancy working party and report on "Broadland", the Civic Trust's recreational plan for the Lea Valley, and the Nuffield-Cambridge survey of common lands.

While these conferences and projects contributed encouragingly towards giving practical shape to the ideas outlined in November 1963, it was felt that a renewed effort in more depth was needed. This took the form of a second conference, two years after the first, prepared by twelve study groups working intensively within four broad areas; legislation and administration; users and uses of the countryside; technology and impacts on land; education, training and qualifications; and information.

With the formation of these study groups a new departure began, since their terms of reference were based on needs brought to light by the first conference, while their membership included more than 180 men and women selected partly for their specialized knowledge and partly for their close association with a wide range of bodies most intimately and continuously concerned. Each study group was serviced by a different organization, official or unofficial, including the National Parks Commission (4, countryside: planning practice); the Scottish Development Department (9, countryside: planning and development in Scotland); the Forestry Commission (3, technology in conservation); the National Coal Board (12, reclamation and clearance of derelict land); the Lincolnshire (parts of Lindsey) County Council (8, preservation of natural, historic and other treasures); the Town Planning Institute (1, training and qualifications of planners); the Royal Institute of Chartered Surveyors (2, training and qualifications of the professions concerned with land and water); the Council for Nature (5, review of legislation); the National Council of Social Service (11, living and working in the countryside); the Automobile Association (7, traffic and its impact on the countryside); the National Benzole Co., Ltd. (10, information and the countryside).

All these study groups worked simultaneously to complete their reports by July 1965. Their devoted chairmen and convenor secretaries formed, together with the organizing committee of vice-presidents, sessional chairmen, joint secretaries and others, a central steering group, served administratively by the Royal Society of Arts and on matters of programme and content by the Nature Conservancy. Thus, of about 360 who participated in the final plenary sessions of the second conference, some 50 had actively assisted in its organization, and nearly 150 more had worked on the preparatory study groups from many different points of view, and had taken part in the lively and critical review of the findings as a

whole during the first two days (November 10 and 11). It appeared, as was to be expected, that this stiffening of seasoned members gave the eventual conference a markedly greater depth, cohesion and focus than that held in 1963, when the majority came new to the subject and to one another.

It had been expected that some study groups would not merely overlap in their coverage, as they rightly did, but would reach conflicting or inconsistent findings, which, with negligible exceptions, they did not. The difficulties which occupied the conference were of a different order, arising from differences in underlying assumptions or emphasis regarding the right scope of the enquiry and the true importance of different elements or interests. Differences also arose regarding the means of fulfilling aims on which all were broadly agreed, and the safeguards for other national or sectional interests affected.

Originally it had seemed that the most urgent and intractable problems might be to resolve differences between voluntary bodies within the naturalist and conservation movement, and between that movement and its potential allies in recreation and among the other 'guardians of amenity', so as to enable the 'conservationists' to speak with one voice to the 'developers'. This presupposed that the 'developers' themselves would become familiar with the issues and be organized not only to express views but also to be able to play an active part in improving liaison, planning machinery and procedures, so as to transform the often negative and time-wasting encounters into a positive and constructive process of reconciling, so far as practicable, conservation with development.

Somewhat surprisingly, it seemed, subject to later confirmation, that these difficulties had been overrated. Since, and no doubt partly owing to, the first conference, it had become fashionable to pay a good deal more than mere lip-service to the overriding need for rapid joint action, and many good examples became manifest. These included the voluntary agreement for withdrawal of toxic chemicals known to be injurious to wild life under certain conditions; the joint policies and practices agreed on by the Forestry Commission; the National Parks Commission and the Nature Conservancy; the surprising unanimity reached by authorities and interests concerned with the Lea Valley and the Norfolk Broads; the progressive outlook of the 'land-linked professions' revealed in Study Group 2; and the almost universal welcome for a broad-based 'Countryside Commission'. The merger of representative bodies for employers and industry in the new Confederation of British Industry opened fresh possibilities of liaison. There was also a marked and most welcome growth in the readiness of planners and planning authorities to envisage substantial changes.

Welcome as were these and other signs of probable progress, they were still outnumbered and outweighed by more adverse factors. The new Regional Boards, too lately constituted to be reliably evaluated yet, were clearly liable to exercise great influence over large-scale development which could fail to take adequate account of the findings of the conference. Nationally it was clear that, in the absence of such impetus as the conference provided, recent tendencies to neglect countryside factors and interests in national planning were likely to continue. It seemed misguided on this basis to argue, as some did, that the scope should be widened to include the whole of urbanization and town planning, the effect of which could only be to relegate countryside problems and interests to a minor place in the only effective forum available to them. On the other flank some, although by no means all, spokesmen of country-dwellers and rural occupations adopted an attitude by no means consistent with the growing trends and impacts, which they seemed to underrate or misunderstand, and which called for much more energetic and thoughtful efforts on their part to reach a new *modus vivendi* with the towns and their recreational, technological and accommodation pressures before it is

too late. While it is only too easy to attract letters to the editor and impromptu speeches and articles from the angle of the country-dweller, there seems to be a severe dearth of thorough study and critical thought by country-dwellers themselves about present-day and impending impacts on the countryside. While this situation persists it helps no one to coin slighting descriptions of academic and other contributors who try, as best they can, to throw some light on these dangerously neglected problems.

Another problem area in this regard is education, and some feeling was aroused by the suggestion that the educational world had not been approached to participate, or that it had been approached in the wrong way. In fact, although every other major national interest approached, from administration (national and local) and angling to women's institutes and youth hostels, responded to the call, it proved impossible, even with patient, tactful and persistent efforts in many quarters, to obtain leading representatives of the teachers who bear so great a responsibility and dispose of such great resources and potentialities regarding the future of the countryside. It is to be hoped that the leaders of this great profession will soon awaken, and that meanwhile they will discourage suggestions that their help has not been invited, which are very far from the truth. Meanwhile, fortunately, such bodies as the Field Studies Council and a number of local education authorities and training colleges are demonstrating how much can be done where the vision and the will exist.

Among problems which remain to be seriously faced are the study of resource economics, including the adequate development of cost/benefit analysis in relation to recreational uses, the future relation of industry to the countryside, tourism in relation to domestic, educational and recreational policies, and the implications of a national land-use policy based on multi-purpose use and zoning principles. Others include land requirements for defence purposes and the role of research in both the natural and the social sciences on human impacts on the natural environment. It is to be hoped that the Natural Environment Research Council and the Social Sciences Research Council will be able to stimulate more adequate work in these fields.

So far as practicable, the Countryside Conferences have been based on assembly of data from research and investigations, supplemented by fresh work wherever time and resources permit, and brought into focus on emerging problems as a basis for the disciplined discussion of the issues and of possible recommendations by selected groups deliberately drawn from a wide range of professions and interests. Much of the knowledge used was either new, unused or under-used previously, and it therefore led to an unexpectedly wide and rapid advance in understanding of the problems. For example, the report of Study Group 3 assembles a range of selected factors in technology relevant to the countryside which make possible a new and more comprehensive view of modern environmental management. Not only the results of the Conference, but the means by which they were reached, will repay investigation.

No other country has yet attempted such an approach. The nearest has been President Johnson's White House conference on "Natural Beauty" in May 1965, but this, although most impressive of its kind, was very lightly documented and was preoccupied with urgent legislation and administrative action, much of which has long been taken in Britain. It is, however, to be borne in mind that documentation on such aspects as recreational pressures and water resources is vastly fuller and more advanced in the United States than in Britain. There is, however, no scientific organization elsewhere in the world looking systematically at problems of the natural environment and the impact of man on it. Without such a basis anything quite like the conferences on "The Countryside in 1970" would not be possible.

MALARIA AND THE OPENING-UP OF CENTRAL AFRICA

IN his inaugural address to the University College of Rhodesia and Nyasaland, Prof. Michael Gelfand took the opportunity to review the part which malaria played in delaying the opening-up of Central Africa to European traders and settlers¹. His original paper is illustrated with reproductions of some fine contemporary pictures which add to the interest of the text.

The earliest in the field were the Portuguese, who were setting up trading posts along the west coast of Africa as early as 1443. Somewhat later they were establishing footholds along the east coast too, but the 'Angel of Death' effectively blocked their penetration into the interior. When quinine became available, the Portuguese took to it more readily than the British and put it to more effective use. Its introduction, although spread over a longer period of time, "had an impact on medicine similar to that of antibiotics to-day".

The legend that cinchona bark was introduced to Europe by the Countess of Chinchon, wife of the Viceroy of Peru, has been convincingly disproved. What is clear is that Jesuit missionaries were in contact with Indians who were aware of the medical properties of cinchona bark, at Loxa, in Brazil, and in Peru, about the beginning of the seventeenth century. Its first recorded importation into Europe was made by Barnabe de Cobo, after exploring parts of Mexico and Peru in 1632. News of it soon spread from Spain to Italy and the Netherlands, and it was introduced to England by James Thomson of Antwerp in 1650.

In many places its acceptance by doctors was very varied, in part perhaps on religious grounds, but in England, resort to its use was stimulated by some serious epidemics of ague, so that the weekly publication *Mercurius Politicus* could report that, by 1658, the bark was on sale by several London chemists. Its fame was heightened by Robert Talbot, who among many others treated King Charles II and the Dauphin Charles of France. He made a fortune out of its secret use. Sydenham was convinced of its efficacy as a medicine, and administered the powdered bark mixed with red wine. As early as 1659 Willis found that the bark relieved acute attacks of ague, although relapses were common; and it was not until 1768 that James Lind observed that, in cases of fever, the drug was most effective if given early in large doses.

In 1745, Claude Touissant de Cagarage attempted to produce an extract of quinine, as did Bernadino Antonio Gomes, of Lisbon, in 1810. Ten years later, Pierre Joseph Pelletier and Joseph Caventou were the first to isolate two of the four alkaloids in the substance. This discovery so stimulated the demand for cinchona bark that exploitation of the forests of Peru, Ecuador and Bolivia was carried to such an extent that fears arose about their exhaustion; the English and the Dutch took up its cultivation, and by 1862 the Dutch had almost established a monopoly in its supply, mainly based on Java.

In comparison with the Portuguese, the British were slow in making attempts to trade with or settle in Central Africa. One of the earliest schemes for settlement was made by William Bolts; it was sponsored by Maria Theresa of Austria. The expedition set out from Leghorn in 1776. It consisted of 152 Europeans, who set up stations along the Masoomo River, in Delagoa Bay, but malaria soon made its presence felt; local Africans rose against the enfeebled party, which was later attacked by the Portuguese, and within three years the entire scheme had collapsed.

These experiences might be taken as representative of a series of disasters which were to follow. About that time some people thought that the Niger joined up with

the Nile, others that it had a confluence with the Gambia River. To explore the Niger, the British African Association sent out a Major Houghton, but he, after travelling through the kingdom of Bamouk, was robbed of his possessions and later died. His task was taken over by a Dr. Mungo Park, who left England with two servants in 1795. He reached the Niger in 1796, followed it for 300 miles, and then, emaciated with fever, returned home.

In 1803 Mungo Park led a fresh expedition. This time he asked for a mosquito net and two pairs of trousers for each man. The party left England in 1805; and, after having to contend with malaria, dysentery, incessant rain, swollen rivers and mud, they reached the Niger. There they built a schooner, and sailed down the Niger past Timbuktu, after which the boat capsized and all were drowned. Of the 44 Europeans in the expedition, 35 died of malaria.

An expedition financed by the Navy and led by Captain James Kingston Tuckey set out from England in 1816. The party entered the mouth of the Congo, and some members worked their way up the River as far as Soondy Nsanga, 280 miles from Cape Padron, where, stricken by disease, they had to abandon all hope of progressing farther. Of the 44 Europeans in the party, 18 died of malaria. Dr. McKerrow, a member of the team, gave a good description of the symptoms of malaria. He noticed that the men most seriously affected were those who had visited African villages or slept in the open. As a medicine he made some use of cinchona bark, but only as a last resort, and the results were unpromising.

Another expedition, sponsored by the Admiralty, left England in 1822, with the view of exploring the east coast of Africa, Madagascar and parts of Arabia. A small detachment attempted to make its way up the Zambesi, reaching as far as Senza. Of the three Europeans in the group, one had already died, and the other two died on the journey back to their base.

The failure of the Congo expedition, sent out in 1816, intensified the desire to solve the problem of the Niger. In 1822 Hugh Clapperton with two companions set out to cross the desert from Tripoli. They discovered Lake Chad; then Oudney, one of the group, died, leaving Clapperton to struggle as far as Sokoto by way of Kano, whence he was able to return alive.

Clapperton made another attempt in 1825, with five Europeans in the party. From the Bight of Benin, one of the group reached Yaourie before being murdered by his followers. The remainder went on to Jannah, where they were all ill with fever; but against formidable odds, Clapperton reached Eatunga, crossed the Niger, and moved on to Kano. Weakened with dysentery and malaria he died at Sokoto, so that, of the Europeans, four died.

At about the same time, a further expedition set out to reach the Niger by way of Tripoli and Timbuktu. It was led by Major Alexander Gordon, who was the first known European to reach Timbuktu, but he was murdered by Arabs soon afterwards. In 1827, a Frenchman, René Caillié, starting from Freetown, reached the Niger and became the second European to see Timbuktu; he succeeded in returning to France alive.

The riddle of the Niger still remained unresolved. To solve it, Richard Lander, who had been a member of Clapperton's expedition, and his brother, John, offered their services to the British Government. They left Portsmouth in 1830, followed Clapperton's route as far as Bussa, and set sail down the Niger with four negroes as a crew. They reached Eboe, near the Atlantic, but were then captured by Ibu traders and held by different people

until finally released, when they found their way to the Atlantic along one of the subsidiary channels of the Niger delta. A boat picked them up and took them to Rio de Janero before they could return to England. They had been advised to take two to five grains of quinine every six hours.

Interest in the Niger rose still higher. A company at Liverpool financed an expedition which was led by Richard Lander and had the use of three small steam-boats. Special attention was paid to the physique and fitness of the crews. But before the ships reached the Niger, fever began to take its toll. Moving up to Ebboe, two of the boats were surrounded by dense vegetation and swamps on either side, and the men were exposed to relentless rain and "torrents of sandflies and mosquitoes".

Further up stream, one of the boats, the *Quorra*, ran aground and remained stuck fast from November until the following March. At the end of March, MacGregor Laird penetrated up stream as far as Fundah, but got no further, and what had been the supply ship, the *Alburkah*, reached Raba and then turned round. At the end of two years, of the total European complement of the three ships, numbering 82, 64 were dead.

By this time the British Navy was active along the west coast of Africa, attempting to suppress the slave trade. Some indication of the health risks to which the crews were exposed is conveyed by the fact that in 1834, of 792 men serving in seven British ships, 204 died. Nevertheless, in 1841 the British Government and members of the public jointly financed the Great Niger Expedition. Three special ships were built, with the *Wilberforce* joining them later. Each boat had a special system of ventilation: during the night as few men as possible were to remain on deck, and when up river, all the white crew had to sleep below. Special clothing was provided, and dry clothing was to be readily available. The men selected were all robust and in the prime of life.

The ships left Woolwich in 1841, and in August, entered the Niger. On September 4 a virulent attack of fever struck the crew of the *Albert*; soon after, the *Soudan* was sent down stream with all the sick. In October the plan to reach Raba was given up. Sickness and deaths continued so that the British Government decided to recall the expedition. Of a total of 145 Europeans, 42 died—almost all of them of malaria.

In his book on this expedition, M'Williams, surgeon of the *Albert*, reported that the practice of blood-letting, which had been the procedure of first choice for almost all the earlier expeditions, was of no value whatsoever, while quinine given at a late stage and in large doses was of some benefit; but he missed the point, which his own records would have shown, that quinine was more effective if given early. He gave details of eight autopsies in each of which he found the gall bladder distended with bile, "the colour and consistence of tar". The colon was generally empty except for "dark pultaceous matter viscid and tenacious".

By this time it was obvious that Africans were much less susceptible to malaria than Europeans, although these too became more resistant if they lived in the country for long periods. This realization, along with a better appreciation of the value of quinine, marked the turning-point in the opening-up of Central Africa. Quinine had been put to medicinal use in the Navy by Sir William Burnett, although it was not given a fair trial. But Alexander Bryson, who was later to become Director General of the Naval Medical Service, recommended that it should be used as a prophylactic and administered to all members of crews on going ashore and on their return, as well as to those who remained on board in swampy places.

With considerations like these in mind, a new vessel, the *Pleiad*, set sail from Plymouth in 1854, under the command of Mr. Beecroft—later succeeded by Dr. William Blaikie. With 12 Europeans and 53 coloured men on

board, it entered the mouth of the Niger and travelled as far as Tshomo; scurvy broke out among the crew, yet although the Europeans were subject to great fatigue and went ashore in unhealthy places, while some of them slept on deck, none of them died. They took three to four grains of quinine every morning, and sometimes in the afternoon.

At this stage David Livingstone came into the picture. It was through reading M'Williams's account of the Niger expedition that he devised his famous pill, consisting of quinine and purgatives. That was in 1850. With it he first treated an English party and members of his own family. His procedure was to give doses large and early; by means of it he was able to cross Africa from coast to coast. His confidence in the pill was so great that he severed connexion with the London Missionary Society, so that he could operate on a wider scale.

By then a national hero, Livingstone had no difficulty in persuading the Foreign Office to sponsor an expedition to ascend the Zambesi as far as Chobe and plant a mission somewhere near the Batoka plateau. When the party reached Africa the members took two grains of quinine every day. Livingstone doubted if that was enough, but he felt that he could stave off serious attacks of fever by extra doses. Altogether, at first things went fairly well in spite of personal dissensions, and in spite of the fact that with a good deal of malaria about, some individuals became more seriously affected. Livingstone also believed in the therapeutic value of physical exertion.

In April 1859, he discovered the Shire Highlands, and in September, Lake Nyasa. Soon afterwards he heard of the fate of the Helmore-Price expedition to Linyanti—an 'unhealthy place'. There was no medically trained person in the group, and out of nine Europeans, six lost their lives.

Further experience of malaria, to which Europeans made a varying response, induced Livingstone to abandon the prophylactic use of quinine for a time. He ran into difficulties over the U.M.C.A. Mission at Magomero, and a series of disasters followed, including the death of Bishop Mackenzie, who lost his supply of quinine when a boat capsized. Worse was to follow: Livingstone's wife died of malaria; the Mission at Magomero, which had been moved to Chibisa, had to be closed down, and he was recalled to England.

The two doctors, John Kirk and Charles Meller, now with extensive experience of malaria, realized that the disease was not so simple as Livingstone had imagined. They identified the dysenteric kind called 'blackwater fever'. Meller distinguished the asthenic and hepatic forms, and experience convinced him of the prophylactic value of quinine, with doses of up to five grains taken daily.

The next steps in the conquest of malaria are more widely known. In 1880, Laveran, a French Army doctor, discovered the cyst-like bodies of the protozoon in the red corpuscles of human blood. This observation was only slowly taken up, but it was confirmed by Marchiafava in 1884; and in 1889, the tertian, quartan and malignant types of the disease were distinguished. Following the discoveries of Manson and Theobald Smith, that insects can act as vectors of disease, on Manson's suggestion, Ross, a British Army doctor, started work in India, and in 1897 found the oocyst in the outer wall of a mosquito's stomach. He worked out the life-cycle of the avian type of the plasmodium in the following year.

Up to 1914, quinine was the only drug known to be effective against *Plasmodium falciparum*, *P. vivax* and *P. malariae*, but not against the gametocytes. The outbreak of the First World War stimulated the search for other preventatives, particularly in Germany where supplies of quinine might be cut off. An observation by Guttman and Ehrlich, in 1891, that methylene blue had some action against the plasmodium served as a starting-point for Schulemann, who after a series of trials synthesized plasmoquin in 1925, the first artificial anti-malarial.

The discovery of atebirin soon followed. This proved to be a valuable drug for prophylactic use in the Second World War. Still more potent drugs, chloroquine and amodiaquine, were isolated shortly afterwards. These two are excellent, having a complete prophylactic action against almost all forms of malaria, while producing no side-effects. Two further anti-malarials to be discovered were proguanil and pyrimethamine ('Daraprim'), the latter being particularly long-lasting. It was discovered by George Hitching of the Burroughs Wellcome Laboratories.

The conquest of malaria has also been greatly assisted through the use of insecticides, such as pyrethrum, Paris green, benzene hexachloride (BHC) and DDT. In the case of some of these there was long delay between their first discovery and exploitation. BHC, for example, was isolated by Faraday in 1825, yet its insecticidal properties were only discovered in the United States in 1933; and a German chemist, Zeidler, synthesized DDT in 1874, yet its properties as an insecticide were first noticed by Paul Müller in the Geigy Laboratories, in Basle, in 1939. The Second World War did a great deal to stimulate the production and exploitation of these compounds. As an example of insecticidal potency, one might mention BHC, which six months after application on mud walls is capable of killing 80 per cent of *Anopheles gambiae*.

Taken together, all these developments have completely transformed the situation in relation to the conquest of malaria. In Nyasaland, for example, as late as 1897, the death rate among European settlers averaged between 9 and 10 per cent, mainly from fever, in a young population. In Northern Rhodesia, during 1907-08, the death rate from malaria and blackwater fever combined was 30.4 per 1,000; in 1925, even before the aforementioned developments, it had fallen to 2.8.

Such results can be compared with those associated with the construction of the Kariba Dam, which was started in 1956 and completed by 1960. Not once was work held up or even interrupted because of disease. This huge under-

taking involved the importation of enormous numbers of African workers from many parts of the country and the employment of many Europeans who had not previously built up any immunity through exposure to malaria. For health and comfort, the living quarters were placed on high ground. All workers were informed about the dangers of heat stroke, and employers were encouraged to allow their workers a period for acclimatization. A survey of the locality showed a spleen rate of 80 per cent, and a parasite rate of more than 30 per cent among the original, local community. All the interior walls of dwellings were sprayed with BHC, and this procedure was repeated three times a year.

As a preliminary measure, an attack was made against mosquito breeding-places through spraying with 'High Spread Malariol' (Shell). Survey counts showed that the operation was effective, so that there was no need to repeat it later. All workers were required to take the prophylactic drug with which they were provided—at first, 0.4 g of camoquin weekly for the Europeans, and 100 mg of mepacrin for the Africans. Later, daraprim was substituted at the rate of 25 mg each per week.

All windows of the European houses were screened, and this helped to keep away millions of other insects as well as mosquitoes. As a consequence, there was not one death from malaria among Europeans living on the site during the first two years. There were two deaths, however, of men living in temporary camps outside the recognized limits, and nearly all the European cases of fever gave a history of irregular prophylaxis, or fishing or hunting at night beyond the controlled area.

These results show that apart from human factors, in Central Africa the conquest of malaria is now almost complete. They also show that in Africa it is a mistake to think of medicine in terms of individual territories.

APPLIED SCIENCE IN THE SCHOOLS

IN recent years a recurrent theme in discussions of science teaching has been the inability of courses in applied science and engineering at universities to attract the best students. This has led to a good deal of self-analysis and exposition of their aims by engineers, and to attempts to acquaint science and careers masters with the nature and purposes of these courses. More fundamental questions are those concerned with changes in the nature of school science teaching itself, and some of the great interest in the new pure science syllabuses of the past few years has now shifted to the possible introduction of applied science courses at school level. This concern led the Institution of Mechanical Engineers* to ask Mr. G. T. Page to assemble a report on the present situation in schools, and in a very short time he produced a mass of information and ideas, obtained both by direct visits and by a postal survey, collated, compared and summarized into an urgent, highly relevant volume.

A conference in October, to discuss this report, showed a very high degree of interest in the whole subject and also produced very complimentary estimates of the report itself, and it is certain that it is at present exercising headmasters and many educational authorities throughout the country. Mr. Page labels his book as descriptive rather than prescriptive, and a large part of the 328 pages is taken up with detail of what is done in a number of schools, both in terms of actual teaching of applied science and 'application-conscious' teaching of physics and chemis-

try, with syllabuses, details of projects, costing and much more important information, both in the text and in appendixes. A lot of space is devoted to the best known experiments in the field, such as the Technical Activities Centre at Sevenoaks School, the examined project work at Dauntsey's School, and the sixth-form courses in applied science such as that at Ealing Grammar School. However, the report is much better regarded as a digest of many different opinions about, and aspects of, the whole subject. There are, for example, chapters on 'Engineers as Teachers' and 'Workshop and Laboratory Technical Assistance', and a provocative section called 'What the Universities Really Think', in which the widely different views of many authorities are contrasted. Throughout, one finds figures, data of all kinds, and tables and photographs of typical laboratories as a basis for further discussion and investigation. In the final chapter, thirty-one suggestions of possible definite actions are made, ranging from joint industrial/school associations to long-term curriculum research. Two particularly interesting lines of argument emerge. One is that it was everywhere insisted by schools who have begun applied science courses that this was done for educational reasons rather than vocational reasons (although some comment in Scotland was less altruistic). The Crowther Report suggested that for many schoolchildren, the 'alternative road' to interest in scientific and technological matters is the most attractive one, and in many cases it has been stated that applied science has been introduced to make school science in some way less dull. Generally, it is true to say that there has been in the past, and still is, in school courses, a pre-

* The Institution of Mechanical Engineers' *Engineering Among the Schools: Activities in Applied Science and Engineering—a Survey of 290 Schools*. Pp. 328. (London: The Institution of Mechanical Engineers, 1965.)

ponderance of analytical rather than synthetic or creative work, a tendency to measure an effect rather than to make use of it; new courses, especially, say, those of the Seven-oaks type, can be more properly regarded as introduced to redress this lack of balance. This kind of response may automatically help to foster the kinds of attitude one would look for in successful engineers, but has not specifically been introduced for this purpose.

Yet, secondly, a good deal of play is made of the reluctance of headmasters to accept that the 'alternative road' into a scientific career might be the best one for some of the best students. This necessarily brings to mind many thoughts about educational attitudes in the country, and the concern of engineers with their own 'public image', especially in the eyes of science teachers counselling boys and girls when they consider university courses. If one considers the diversity of activities under the broad head of engineering and technology, it is perhaps not too surprising that this image is a little out of focus, but the present careful expositions of the need for flexibility, breadth and social and economic awareness in an engineer may alter this. If a teacher is able to consider an engineer as a bridge-builder between two cultures, rather than a glorified technician, he can then be more inclined to satisfaction at the prospect of the best intellects entering engineering careers. The objections by a number of authorities to the idea of A-Level examinations in applied science make good sense when one considers the present-day attempts to ask for more flexible university entrance requirements, and the talk of a single chemistry-

physics A-Level subject. At the same time, the investigations of approaches to technological studies at sixth-form level and the centralization of such work by the Schools Council are very welcome. What seems vital is that any teaching institution should be concerned, within the general framework of science courses which its size and resources allow it to offer, to present as wide a picture of what the whole effort of scientific and technological work consists of, as is possible, whether this be through complete courses in large schools, or project work, or re-orientation of existing pure science into application-conscious treatment. This is particularly true, if like the Nuffield Scheme co-ordinator, one regards a sixth-form course as being a final chance to sample disciplines; it will be of very great interest to see the eventual content of the Nuffield A-Level courses. Help which can be obtained, through curriculum research of any kind, for example, is obviously most important in all circumstances.

In any event, the Page Report, making available detailed information, opinion and informed suggestion, is a key document for anyone concerned in decisions about school science courses. In addition, it is eminently readable, and, despite the rapidity of its publication, excellently produced. It is possible that it may be the preliminary to further substantial changes in school work, and it will certainly help the careful thinking about this rather complex subject which is needed while school science is altering at the present rapid rate.

T. A. BURDETT

CHEMICAL PHYSIOLOGY OF THE ACID MUCOPOLYSACCHARIDES

ALTHOUGH there have been several excellent symposia on connective tissues, it is now too big a subject to cover adequately in a meeting of manageable size, and its various compartments tend to be treated separately. The acid mucopolysaccharides have been quite fully discussed from the metabolic and chemical aspects, but not often from the point of view of the chemical physiologist. This is not surprising, since the state of combination of acid mucopolysaccharides in tissues was unknown, their localization depended on primitive and non-specific techniques, and practically nothing was known of their molecular biology. Considerable progress is being made on all three problems, and it was thought that the results would support a three-day meeting, with ample discussion.

The symposium was organized by Dr. Giuliano Quintarelli, of the University of Alabama, and held under the auspices of the Carlo Erba Foundation in Milan during September 23-25. Travel grants were made available by American Chicle Co. and Colgate-Palmolive Co. through Dr. J. Volker, vice-president of the University of Alabama Medical Center.

Seventeen speakers were invited, several of whom comprehensively reviewed their subjects in addition to presenting new data. Dr. Helen Muir (St. Mary's Hospital, London) opened the proceedings with a paper on "Protein-Polysaccharides", and was followed by Dr. L. Rodén (University of Chicago) on "The Protein-Carbohydrate Linkages of Acid Mucopolysaccharides". Dr. Rodén presented the evidence that chondroitin sulphate A is linked to protein by means of a glucuronosyl-galactosyl-galactosyl-xylosyl-serine bridge, with much detail on positions of glycosidic bonds, etc. Dr. P. Hoffman (Research Institute for Skeletomuscular Diseases, New York) discussed threonine, serine and asparagine as alternative linkage points for the polysaccharide at the protein. Dr. Hoffman took up a theme introduced by Dr. Muir (frequently mentioned during the meeting) as to how heterogeneous the cartilage protein-polysaccharide

is, and showed that his preparations contained chemically dissimilar fractions, separable on electrophoresis.

Papers by Dr. Castellani (Pavia) and Drs. Pedrini and Pedrini-Mille (University of Iowa) dealt with the keratan-sulphate-protein complex from epiphyseal plates and human costal cartilage, respectively. Dr. Pedrini reported three components in his water extracts, as shown by electrophoresis on cellulose acetate, the slowest being predominantly the keratansulphate complex, and the fastest the chondroitin sulphate complex. The ratio of the slowest to the fastest increased with age. They differed significantly in their amino-acid content. Dr. J. D. Gregory (Rockefeller University, New York) described countercurrent fractionation of the hyaluronidase digested cartilage protein-polysaccharide. Two components were isolated, one containing the keratansulphate, and the other remnants of chondroitin sulphate attached to protein. Dr. N. di Ferrante (University of Texas), in the course of a review of the "Antigenicity of the Protein Polysaccharide Complexes from Cartilage", presented evidence that the keratansulphate-protein fragment of Dr. Gregory possessed the antigenic properties of the original protein-polysaccharide. The second fraction of Dr. Gregory, containing remnants of chondroitin sulphate, was not antigenic.

The papers of Dr. S. M. Partridge (Low Temperature Research Station, Cambridge) and Dr. D. Dziwiatkowski (Rockefeller University, New York) dealt with the effects and the isolation, respectively, of an enzyme present in cartilage which proteolytically degrades the protein-polysaccharide. The implications of these findings to the study of the complex are great, and probably much of the work already done will have to be reassessed. Dr. Cifonelli (University of Chicago) rounded off this section by pointing out areas in which chemical investigations had turned up conflicting data, and discussed degradative techniques which could resolve the difficulties.

Dr. T. C. Laurent (University of Uppsala, Sweden) opened the 'molecular biology' section with a demon-

stration of the importance of the 'excluded volume' and 'available volume' concepts in this field. The interpretation of the physiological role of the acid mucopolysaccharides is likely to draw heavily on this work. Dr. E. A. Balazs (Retina Foundation, Boston) considered the role of polyanions in the transformation of chemical to mechanical energy in a paper entitled "The Mechanochemical Function of Mucopolysaccharides in the Organization of the Intercellular Matrix". Dr. J. E. Scott (Taplow, England) reviewed "Ion Binding in Solutions containing Acid Mucopolysaccharides" and suggested that Coulombic complexes of proteins and acid mucopolysaccharides could be 'ion-buffers'. Work on the "Interaction of Collagen and Acid Mucopolysaccharides" was presented by Dr. M. B. Mathews (University of Chicago).

The microlocalization section was introduced by Dr. G. Quintarelli (University of Alabama) in a review of relevant histochemistry which demonstrated that little reliance could be placed on previously accepted techniques. Dr.

J. E. Scott (Taplow, England) described how the "critical electrolyte concentration" phenomenon could be used to investigate and improve on the specificity of cationic dyes. In the final paper, Dr. S. Gardell (University of Lund, Sweden) compared the results of the best available mucopolysaccharide fractionation techniques for the analysis of microgram quantities of tissues obtained by microdissection.

The chairman of the concluding session, Dr. E. A. Balazs, thanked the organizers and particularly Dr. Sirtori and the Carlo Erba Foundation for their magnificent hospitality; the participants joined in complete agreement. This was the first full three-day symposium in English to be held at the Carlo Erba Foundation, and everyone present will wish for the opportunity to be present at others in the future.

The *Proceedings* will be edited by Dr. Quintarelli and published in book form by Little and Brown, Boston.

J. E. SCOTT

POSSIBLE CONTRIBUTION OF JUPITER'S MAGNETOSPHERIC TAIL TO THE RADIO EMISSIONS OF THE PLANET IN THE DECAMETRIC REGION

By G. M. GRUBER

Department of Physics, Rhodes University, Grahamstown, South Africa

SINCE Bigg¹ showed that the satellite Io influences the decametric emission it seemed promising to look for dependences which are not related to the rotation of the planet Jupiter. Prof. J. A. Gledhill suggested to me that it might be interesting to investigate the possibility that radiation from Jupiter's magnetospheric tail contributes towards the decametric noise.

Since the data obtained at our research station were insufficient for any large-scale investigation, the obvious choice was the data of J. W. Warwick and W. T. Kreiss² compiled from observations during January 1, 1960–December 31, 1963. In addition, Drs. Warwick and Dulk supplied me with the data obtained during January 1, 1964–May 31, 1965, for which I thank them.

In their data they recorded the U.T. start and finish of each observing period and of each Jupiter event, its frequency range, intensity (on a scale of 1, 2 and 3), the burstiness as weak, moderate or strong, and the System III CML (Central Meridian Longitude) of each event.

To find whether any influence of the magnetospheric tail existed, the following procedure was adopted. The period between two superior conjunctions was divided into 27 intervals each of 15 days, except for the first and the last which have less than 15 days. The intervals were numbered from -13 to +13; interval 0 was centred on the day of opposition. For each of these intervals the total time for which Jupiter was observed was computed as well as the total time during which Jupiter events occurred. The ratio of the latter to the former gives the percentage probability of occurrence for that particular interval. (No notice was taken of the frequency distribution of the bursts.) The number of events during the five apparitions were 57, 247, 354, 429 and 229 respectively. The results for each apparition are shown in Figs. 1–5.

On combining the values for the five apparitions, that is, calculating the average percentage probability for correspondingly numbered intervals, a most interesting result is obtained (Fig. 6).

From the graph it appears that the percentage probability of observing decametric emission is much higher before opposition than after opposition, the ratio being approximately 3:2. Furthermore, a sudden 'cut-off' after opposition is evident.

G. A. Dulk³ has drawn up histograms for the first and second half of the apparitions of 1963 and 1964. The higher probability of occurrence is quite noticeable, and he suggested that the difference might be attributed to the

Fig. 1. Percentage probability versus interval number for 1960

Fig. 2. Percentage probability versus interval number for 1961

influence on Jupiter reception of the maximum usable frequency of the Earth's ionosphere.

To check whether the cut-off frequency of the ionosphere has any noticeable influence, the 'mean lowest frequency' observed was calculated for each interval for the five

Fig. 3. Percentage probability versus interval number for 1962

Fig. 4. Percentage probability versus interval number for 1963

Fig. 5. Percentage probability versus interval number for 1964

Fig. 6. Percentage probability versus interval number for the five-year period 1960-1964

Fig. 7. 'Mean lowest frequency' versus interval number for the five-year period 1960-1964

apparitions. This was done by noting the lowest frequency observed and totalling over the fifteen days interval, the sum then being divided by the number of events in the interval. The results were plotted as Fig. 7.

From Fig. 7 it seems obvious that the variation of the mean lowest frequency observed does not account at all for the large drop in percentage probability after opposition. The steady level reached in Fig. 6 from interval 2 to interval 8 emphasizes the discrepancy.

Furthermore, it can be seen by comparing Figs. 6 and 7 that the rise in percentage probability starting at interval -10 and the fall of percentage probability starting at interval +8 can be explained by the rise in cut-off frequency.

The asymmetry of Fig. 6 suggests that the emission from the planet Jupiter does, in a certain way, depend on the relative position of the Sun, Earth and Jupiter, the higher percentage probability of receiving Jupiter noise being before opposition. Such a pattern of radiation can be produced by a magnetospheric tail. The tail, assuming it exists, would be swept back from the Sun-Jupiter line by an amount depending on the ratio of Jupiter's velocity in its orbit to the velocity of the solar wind in the vicinity of Jupiter. This means that the angle which the tail sub-

tends at the Earth would vary with the position of the Earth relative to the Sun-Jupiter line, the tail subtending a larger angle before opposition, the maximum value being reached three months before. If this source is anisotropic a sudden cut-off, such as shown in Fig. 6, might be expected.

Fig. 6 can therefore be explained if one assumes two sources, although they might have similar mechanisms, one closely related to the rotation of Jupiter, and Io related, the other having its origin in a Jovian magnetospheric tail.

WELDING BY HIGH-VELOCITY PARTICLE IMPACT

By DR. ROBERT F. ROLSTEN*

Technical Operations Research, Burlington, Massachusetts

ALAN K. HOPKINS

AND

HAROLD H. HUNT

5965 Manon Street, La Mesa, California

STACKS of target plates have been spot-welded by the hypervelocity impact of a microparticle¹. Parts of the plate surfaces became plastic under the impulsive load and were welded. Metallographic examination of the cross-section of the weld indicated that the structure was rippled². The ripples show a definite crest structure, which may explain the mode of their formation; that is, the movement of the plastic surfaces at different velocities while the surfaces are held together under the high pressure produced by the projectile impact. The ripple effect associated with the welding may be described as "surface jetting", which enhances welding because of the maximum surface friction and the increased contact area at the interface.

In an investigation of these impact spot welds we have conclusively related the weld-ripple phenomenon to the explosive welding of metals as described by Rinehart and Pearson³ and Cowan and Holtzmann⁴ and to the surface jetting described by Walsh *et al.*⁵, Allen *et al.*⁶, and Abrahamson⁷.

Hypervelocity particle impact welding was obtained by firing 0.005-g 'Mylar' cylinders into stacked targets of

Fig. 2. Cross-section of welds. Area indicated by arrow in Fig. 1

aluminium or copper plates or a combination of aluminium and copper plates. In one experiment a target of 1100-0 aluminium plates alternating in thicknesses of 0.064 in. and 0.010 in. was impacted in vacuum by a 'Mylar' projectile at a measured velocity of 28,200 ft./sec. A profile of this target is shown in Fig. 1. Welds were produced between the third (0.064-in. thick) and fourth (0.010-in. thick) plates and between the fourth and the fifth (0.064-in. thick) plates. The wavy, or rippled, interfaces of these welds, shown in Fig. 2, have been attributed to the phenomenon of surface jetting.

Welding did not always occur during hypervelocity impact on a stack of plates. In some experiments the rippled interface and weld were produced, but the weld bond was ruptured by shock in the parent metal plates, and the plates became separated. This forceful separation of a once smooth, rippled and welded structure resulted in a sawtooth and free surface, as seen in Fig. 3. In other experiments a weld did not form or was exceptionally weak, but the mating surfaces, plastic and moving at different velocities, were left with a rippled surface, as shown in Fig. 4.

* Consultant, 5141 Willow Crest Road, Dayton, Ohio.

Fig. 1. Welded 1100-0 aluminium plates. Impact velocity, 28,200 ft./sec. Section at arrow shown in Fig. 2

The target shown in Fig. 4 was a two-plate target consisting of a 0.090-in.-thick plate of 6061-T6 aluminium in contact with a 0.375-in.-thick plate of the same material. It was impacted in air at 15,000 ft./sec by a 0.25-in.-diam. right circular steel cylinder of 0.5-g mass. Fig. 5 is a diagram of the sequence of events which we believe occurred during impact on the target in Fig. 4, which punctured the two-plate target system and produced concentric ripples around the puncture. In Figs. 4 and 5 we have designated the outer boundary of a series of concentric ripples as *A*; the outer boundary of a galled, or chaffed, ring-shaped area, evidently caused by relative motion of the two surfaces while they were tightly compressed, as *B*; and the outer edge of the upward bulge of the surface produced by lateral displacement of material surrounding the puncture as *C*.

The outer radius of the chaffed ring (*B*, Fig. 4) in a two-plate system, by our hypothesis, should be a measure of the time for penetration of the first plate according to the following relation:

$$R_r - R_p = f(V_w, T, E, V_p)$$

Fig. 3. Sawtooth structure produced by forceful separation of welded plates

Fig. 4. Second, or bottom, plate with concentric ripples (*A*), galled ring (*B*), and distorted surface (*C*) referred to in Fig. 5

Fig. 5. Puncture of a two-plate system

Top to bottom:
A shock-wave in the first plate from lateral pressure of the projectile reduces to an elastic wave at *A*, the outer boundary of the ripple pattern. The elastic wave reaches *B*, the outer boundary of the galled ring, as the projectile punctures the first plate. The pressure holding the plates in contact is reversed by elastic rebound and ejecta now moving from the developing crater in the second plate.
The first plate 'petals' under pressure of ejecta from the second plate. Lateral plastic and shock waves are set up in the second plate.
The lateral elastic wave reaches *C*, the outer edge of the upward bulge of the surface as the second plate is punctured.

where R_r is the outer radius of the chaffed ring, R_p is the radius of the projectile on impact, V_w is the wave velocity, T is the thickness of the first plate, E is the elastic recoil of the first plate, and V_p is the velocity of penetration. Data to establish the functional relation are lacking. However, the available data do show that the length of the outer radius of the galled ring is a function of the thickness of the first plate and an inverse function of impact velocity. This has been determined from the experiments with right circular cylindrical steel projectiles 0.25 in. in diameter with a 0.5-g mass fired in air into a stack of two 6061-T6 aluminium plates (Table 1).

We postulate that the ripple structure in Fig. 4 resulted from dynamic instability of the shock wave in the first (top) plate at the interface of the two plates. Material in the first plate was being forced outward radially. The chaffing, or galling, in the area between *A* and *B* was caused by the same shock wave after it had been reduced to an elastic wave. The welling up of the surface, which extends from *B* to *C*, resulted from shock and plastic waves produced in the second (bottom) plate during its puncture. The area between *B* and *C* is not related to the rippled or the galled area since the surfaces of the first and the second plates were no longer in close contact.

Table 1. SIZE DEPENDENCE OF CHAFFED RING ON IMPACT VELOCITY AND THICKNESS OF FIRST (TOP) PLATE

Measured impact velocity, ft./sec	Thickness of first plate (in.)	Radius of chaffed ring (<i>B</i> , Fig. 4) (in.)
9,400	0.090	0.55
15,000	0.090	0.53
14,700	0.1875	0.578

The first plate was forced away from the second plate and deformed in a direction opposite that of the projectile movement by the force exerted by the relief wave sweeping over the upper free surface of the first plate and by the ejecta from the crater in the second plate and to a lesser extent by its elastic reaction to the release of impact pressure. No evidence of welding was noted in this experiment, although the same rippled structure is associated with welding.

In some stacked targets welding has been observed to occur between the first and second plates of the structure and in successive plate interfaces; in other targets the welds did not occur before the second plate and third plate interface. If either the relief wave or the crater ejecta from the projectile and the second and successive layers force the first plate away from the structure, then a criterion for the welds to occur in this first interface must be the tensile strength of the first plate material. A high-ultimate tensile strength material (6061-T6 or 2024-T3) will resist this upward deformation and therefore may enhance the conditions for weldment; whereas a low-strength material (1100-0), being more ductile, may easily deform and tear the interlocked ripple crests and form sawteeth.

The impact energy in the experiment referred to in Fig. 1 was 1.85×10^9 ergs. Complete deceleration of the projectile was accomplished in 0.8475 cm, giving a force of 2.185×10^9 dynes. A circle with a radius of 0.565 cm will include the welds, which yields a surface area of 1 cm². If we assume that the entire impact pressure was applied normal to the target face simultaneously and was evenly distributed over 1 sq. cm, the pressure would be 2.185×10^9 dynes/cm², or 31,750 lb./in.², a direct pressure which we believe to be far below the threshold necessary for welding. The very high pressure contained within the thin expanding circle at the shock-wave front must be the cause for the welding that occurred⁸.

The impact pressure at the surfaces of a two-plate target system forces the target interface surfaces into intimate contact during the time the projectile is moving through the first plate. At this same time, the projectile with the target material directly under the point of impact expands radially and exerts a lateral thrust (cavitation) tending to enlarge the hole in the first plate. The lateral disturbance is propagated as a shock-wave. To permit sufficient heat transfer to induce all parts of the shock-wave to propagate at the same velocity, it is necessary

for the whole wave front to be very thin, or 'steep'. Material in this shock front is highly compressed. The high-pressure wave front sweeping radially outward in the first plate can act across the interface since the surfaces of the two plates are in intimate contact. The inertia of the materials responding to the pressure across the interface creates a dynamic instability in the pressure at the interface due to the alternation of jetting and non-jetting collisions. This causes a rippling of the surfaces as the shock-wave sweeps outward.

The rippling of the surface structure increases the surface area and produces maximum shear, which opens wide fissures in the surface layers of adsorbed gases, reactants, and foreign materials. This dilution and shear effect, combined with the induced turbulence and the high pressures within the wave-front, promotes intimate contact and permits the linking of metal atoms across the interface. If the surfaces are reasonably free of foreign substances and entrapped air, mate well, and are held in firm contact, then bonding may result. This bonding may be enhanced by an interlocking action of the ripples.

The experiments reported here suggest that satisfactory welds can be made in a stacked target with a minimum amount of energy (where the surfaces of the target plates are held in intimate contact under high pressure) by projecting a strong shock-wave to one of the parts more or less parallel to the interface. The conditions for the production of the desired weld are dependent on the plate material, surface condition and thickness and on the strength and propagation velocity of the shock-wave.

We thank the Utah Research and Development Company for performing the hypervelocity impact experiments at the Air Force Materials Laboratory, and Lieutenant W. A. Dean, who conducted the metallurgical analyses of all specimens.

⁸ A shock-wave also results in an embossed surface. A scratch placed across the surface of one plate was observed in raised relief in the mating face. This reproduction of the scratch did not extend into the elastic region; that is, not in the region of BC, Fig. 4.

SEISMICITY AND OTHER PROPERTIES OF GEOLOGICAL PROVINCES

By PROF. E. R. KANASEWICH

Department of Physics, University of Alberta, Edmonton, Alberta

MUCH effort has been expended in sub-dividing the Canadian Shield into suitable units of study. Early classifications¹⁻⁴ were based primarily on stratigraphic, petrological and structural similarities. Features such as parallel fold belts, foliation trends and truncation of ancient orogenic centres by younger mountain belts were invaluable aids in this work. Lately, the classification has been carried out with the aid of geochronological data⁵⁻¹⁴. The classification is now based on the repeated recurrence of certain dates over widespread areas when K/Ar, Rb/Sr and Pb/U dating methods are used. These dates are related to periods of severe metamorphism during which minerals crystallize or recrystallize. Often they can be correlated with similar events on widely separated regions of the Earth.

Most of the geochronological data for North America have been assembled on a large-scale map and the continent has been sub-divided according to the latest available information. References used but not mentioned in the text are listed at the end of this article. The

compilation now consists of nearly 2,000 dates, with the majority being potassium-argon determinations on biotites, muscovites and hornblende. Rubidium-strontium whole-rock ages and lead-uranium concordia and discordia¹⁵ ages were included wherever available. A small-scale copy showing the geological provinces and the general location of the data is reproduced in Fig. 1.

The classification into geological provinces in Fig. 1 and Table 1 is based on the oldest reliable dates present in each area. A certain amount of subjective judgment cannot be avoided and particular points of difficulty are discussed below. When considering the K/Ar data alone, the boundaries proved to be surprisingly sharp considering the presence of over-thrusting, tectonic inliers and the effect of multiple metamorphism along adjacent orogenic belts. When model lead and strontium whole rock ages are also considered the boundaries are less distinct.

So far as possible, secondary features, such as miogeosynclinal mountains, basins and troughs known to be

Table 1. CLASSIFICATION OF GEOLOGICAL PROVINCES BY LIMITS ON RADIOACTIVE AGE DETERMINATIONS

Geological province	Range of age determinations (m.y.)
Superior	3,300-2,300
Slave	2,900-2,200
Churchill	2,300-1,700
Penokian	1,900-1,400
Ozarkian	1,450-1,200
Grenville	1,200- 600
Innuvian	600- 200
Appalachian	550- 200
Cordilleran	350- 0

underlain by older crystalline rocks were not considered in this map. Neither were such igneous bodies as the Duluth gabbro, which has a well-established age of 1,000 million years on the basis of K/Ar, Rb/Sr (ref. 9) and strontium whole-rock analyses¹⁶. This large sill occurs among rocks metamorphosed and folded about 1,700-1,800 m.y. ago and was emplaced in a series of intrusions into these older rocks through fractures formed in response to the severe 1,000-m.y. event which had its greatest effect in the Grenville province 500 miles to the east.

The nomenclature closely follows that used by Stockwell in the Geological Survey of Canada^{12,13}. Gastil¹⁰ recognized that the data indicate the necessity of at least two new geological provinces. The first of these is here called the Penokian⁹ province and includes the large strip from eastern California to Sudbury. It appears to extend into the region of the Purcell Mountains in British Columbia on the basis of model lead ages¹⁷ in the Kimberley, Coeur D'Alene and Kootenay are districts and two K/Ar dates^{18,19}. The Beltian rocks may be underlain by an older crystalline basement, but there is no evidence for this at the present time.

The second new province includes the area between the Penokian and Grenville and is here termed the Ozarkian after the Ozark uplift in south-eastern Missouri where the Pre-Cambrian basement rocks are exposed. The dated outcrops occur mainly in Missouri, Kansas, Texas, New Mexico and Arizona. The major tectonic activity occurred here between 1,300 and 1,450 m.y. ago.

The sub-division of the continental crust is based largely on K/Ar data. A certain amount of caution must be shown in using the results, since the mathematical equations may not model the physical environment of the mineral closely enough. All minerals are susceptible to a certain loss of daughter products during episodes of metamorphic activity. Furthermore, the present Pre-Cambrian surface represents such a deep erosional level that what we now sample in many places are the old mountain roots which were at an elevated temperature during much of geological time. A small but continuous amount of diffusion cannot be discounted without corroborating evidence.

Loss of daughter products will cause the age to be too low. However, a mineral may also incorporate some argon in the lattice during the time of crystallization and produce a measured age that is too high. Richards and Pidgeon²⁰ have observed that some biotites from the Broken Hill district, Australia, yielded ages twice the Rb/Sr ages. Evans and Tarney²¹ report more than 20 whole-rock K/Ar dates on dolerites in Scotland between 1,550 and 3,860 m.y. The Rb/Sr ages on a biotite and a whole-

rock sample are 2,190 m.y. Workers from the Geological Survey of Canada²² have dated a biotite in Newfoundland as 3,730 m.y. with the K/Ar method and 900 m.y. with the Rb/Sr method. These and other reports^{13,23,24} indicate that K/Ar data must be checked carefully. If there are a few dates which are 400 per cent too large, there may be more that are only 10 per cent too large.

A further difficulty which may be recognized is that rocks of clastic origin may occasionally be dated. Thus Burwash and Baadsgaard²⁵ give K/Ar dates of 2,400 m.y. on the basal Nonacho Conglomerate. These lie on a gneissic complex of the Churchill province with biotite dates of 1,800 m.y. The interpretation of dates from rocks which may have been transported long distances is not unambiguous and must be evaluated carefully when considering theories on continental growth^{6,26}.

The difficulties mentioned in the preceding two paragraphs are common to all dating methods to a certain degree. Research workers carrying out the geochemistry and mass spectrometry have recognized these and other difficulties and interpreted their results with caution. Usually a representative suite of minerals is dated and consistent results on cogenetic minerals are given more weight. Samples which satisfy the assumptions built into the mathematical formulae are used in the interpretation. Such caution is not evident in many statistical compilations to determine the 'peaks of orogenic activity'. Histograms showing peaks of K/Ar results are particularly susceptible of misinterpretation since the peak may lag the period of most intense metamorphism due to argon loss in subsequent episodes. Samples from contact metamorphic zones²⁷ are often dated but are difficult to

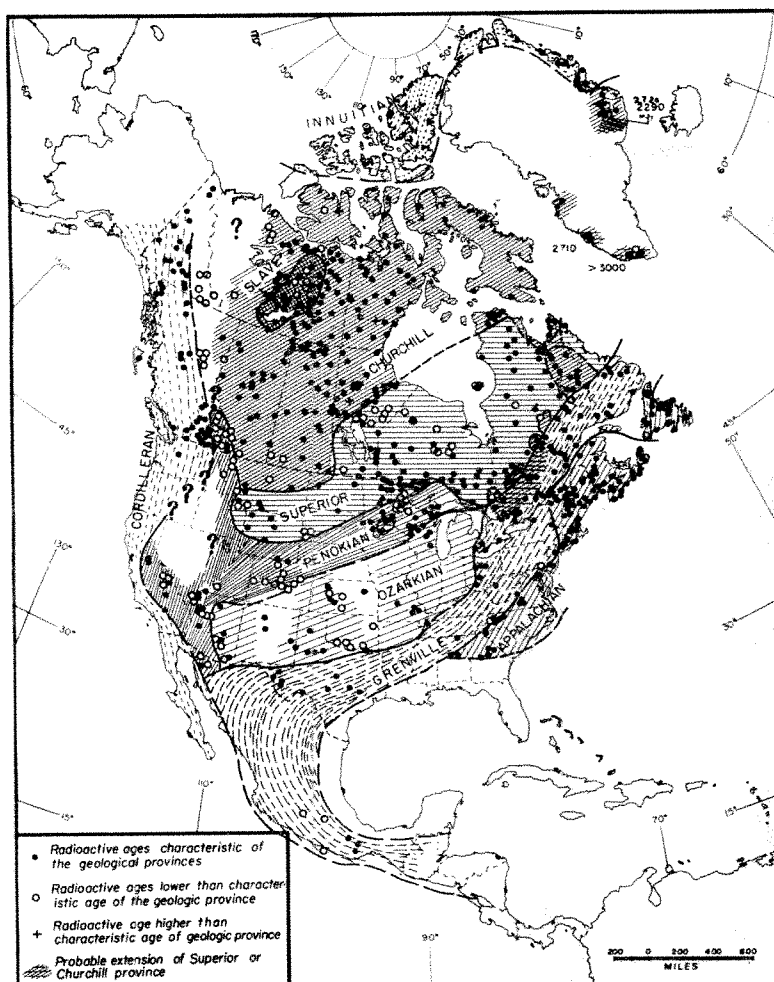

Fig. 1. Geological provinces of North America

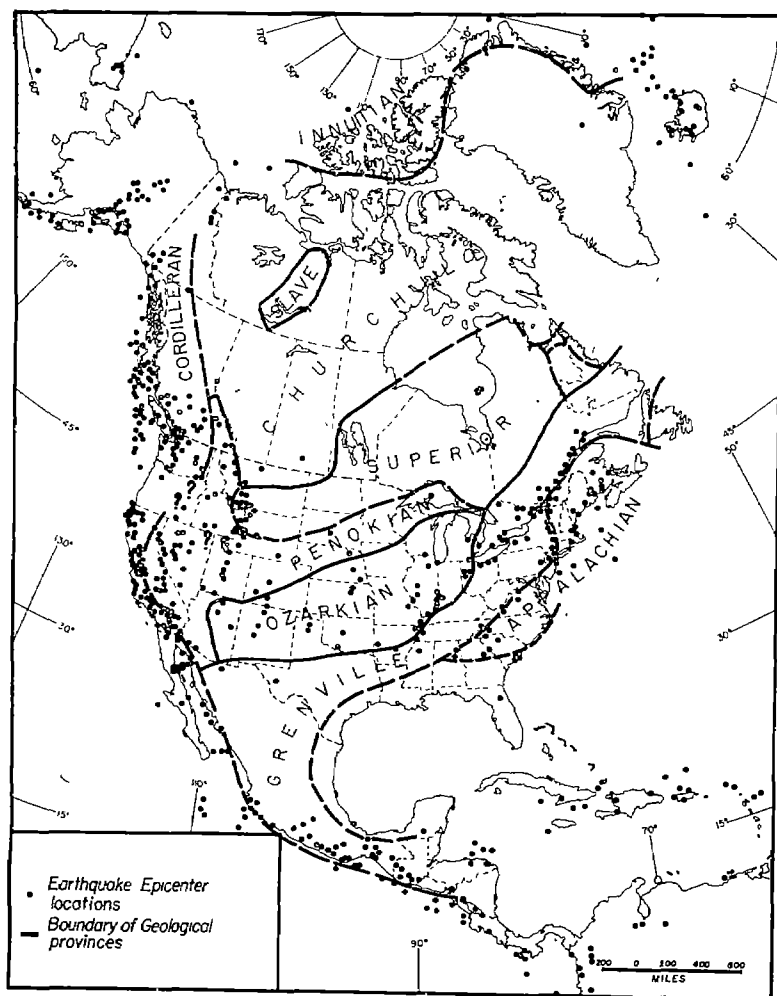

Fig. 2. Instrumentally determined earthquake epicentres in North America showing the correlation with some boundaries between geological provinces

recognize. Until a large amount of Rb/Sr and Pb/U data is available the K/Ar results from the Pre-Cambrian era should be used only in resolving broad regional structure. In particular, caution is necessary in subdividing geological provinces or the Pre-Cambrian time-scale on the basis of such low-resolution data.

An extreme example of the complexity that is possible is illustrated along the southern margin of the Superior province in Ontario and Quebec. There is a group of well-established ages between 1,600 and 2,300 m.y.²⁸⁻³⁰ which may be correlated with early orogenic activity in the Churchill province or late events in the Superior province. From lead isotope evidence³¹ and whole rock strontium results³² it appears that these ages extend into the region classified as the Grenville province on the basis of potassium-argon dates. An attempt was made to indicate the complexity in this area by cross-hatching in Fig. 1. From Fig. 1 it is also clear why the Sudbury area has had such a complicated pattern of ages. It forms the focal point of five geological provinces and has consequently been affected to some extent by orogenic activity in each province.

Several boundaries are the site of rapid and large-scale variations of physical properties. For example, the north-western boundary of the Superior province is bounded by a prominent group of gravity anomalies called the Nelson River high³³. The pattern of arcuate alternating positive and negative Bouguer anomalies is suggestive of the isostatic anomalies along the Indonesian Trench³⁴. Another prominent group of anomalies follows the St. Lawrence River³⁵ and into the United States³⁵ along the

entire length of the boundary between the Grenville and Appalachian provinces. The boundaries of the Slave and Grenville provinces also correlate with aeromagnetic trends. These correlations indicate that the boundaries between geological provinces have played an important part in the development of the continents.

A characteristic of the oldest parts of the continent is obtained from seismic evidence. The area has a very small amount of earthquake activity at the present time. This would seem to strengthen the arguments for continental growth. It is difficult to see why tectonic activity should avoid the oldest portions of North America unless this is a natural sequence of events in the evolution of the continental crust and upper mantle. Similar remarks apply to the moderately sized continents of South America, Australia and Antarctica. The pattern is more complex for the two largest continents of Africa and Asia. Africa, in particular, appears to be breaking apart along the Rift Valleys.

A compilation of instrumentally determined epicentres as reported by the Dominion Observatory, Canada, and the United States Coast and Geodetic Survey is presented in Fig. 2. The depth of the foci under North America is generally less than 70 km, but no attempt has been made to classify the shocks by depth or magnitude. The location of the epicentres may be uncertain by one degree of latitude and longitude for small earthquakes. With the new seismograph network and digital computation facilities now being established, it will soon be possible to prepare comprehensive maps with depth, magnitude and *P* nodal solutions from first motion studies.

The boundaries between several geological provinces have a large amount of earthquake activity. This is more evident on the eastern side of the continent where the level of activity is not so great. Concentrations of earthquakes occur along the boundaries between the Ozarkian, Grenville and Appalachian provinces. There is little information on crystalline basement rocks in the western United States and British Columbia. Consequently the boundaries of the provinces are largely undetermined. The postulated correlation between earthquake epicentres and geological boundaries suggests that elastic stresses may be relieved along the system of faults and fractures which may parallel the boundaries. These fractures probably extend to great depth in the crust and have possibly existed since the inception of orogenic activity along these boundaries.

The North American continent may be divided into nine geological provinces on the basis of the oldest K/Ar, Rb/Sr, Pb/U and model lead ages in the crystalline basement rocks. On this basis it is evident that only a minor amount of continental growth has occurred in the past billion years. The central continental nucleus, called the Superior province, extends from Greenland to Wyoming and was formed more than three billion years ago. The Superior, Slave and Churchill provinces have negligible seismic activity at the present time, and these very old stable blocks must have an upper mantle in which the radioactive elements have been depleted through transfer into the crust to a greater extent than the rest of the continent. Surface wave investigations³⁶ and long-range observations on longitudinal waves³⁷ also indicate that there are significant differences in the upper mantle

under the Canadian Shield as compared with other parts of the continent. Over North America the pattern of ages is defined sufficiently to test the possibility of continental drift. Unfortunately there are insufficient data on other continents to make an evaluation of this hypothesis.

A tentative correlation has been found between the boundaries of geological provinces and zones of earthquake activity. It appears that elastic stresses may be relieved along fractures which extend to great depths in the crust and have existed since the inception of orogenic activity along these boundaries.

CARBON ISOTOPE RATIOS AND PALAEO-SALINITIES OF PURBECK-WEALDEN CARBONATES

By PROF. P. ALLEN

Sedimentology Research Laboratory, Department of Geology, University of Reading
AND

PROF. M. L. KEITH

Department of Geochemistry and Mineralogy, Pennsylvania State University

BIOLOGICAL and lithological evidence leads to the conclusion that the Purbeck-Wealden beds of southern England were deposited in a variable-salinity environment. Salinities apparently ranged from supersaline in the lower Purbeck (evaporites), to near-marine in the mid-Purbeck and upper Wealden (for example, 'cinder bed' members with oysters, echinoids, etc.), to freshwater in parts of the lower and upper Purbeck and lower and upper Wealden (Unio beds, horsetail soils, etc.).

Lateral and vertical fluctuations occurred at these extremes. Thus faunal gradients seem to exist in the Purbeck Cinder Bed¹⁻³, and many individual Wealden laminae are dominated by one genus at a time. On Wealden bedding planes *Unio*, *Viviparus* and *Physa*

tend to be 'incompatible' with *Neomiodon* and *Filosina*, especially among assemblages containing articulated shells. Only *Physa* is known 'at home' among the Wealden freshwater plant communities⁴. If the Wadhurst and Grinstead Clay sequences are partly transgressive they might be expected to show slightly elevated salinities⁵. But the macropalaeontological evidence, though purposely sought, has not been found⁶.

Geochemical evidence of depositional environment is difficult to interpret and unique solutions seem equally unlikely. We are not so sure as Walker⁷ that equivalent boron⁸ is a 'realistic index of palaeosalinity'. Quantitative interpretation of the Purbeck-Wealden environments is complicated by provenance of the sediments. Through

much of southern England they contain derived material (including illite-rich clay) from marine Upper Jurassic sources⁹. Variable proportions of mixed-layer clays¹⁰ and of associated boron could have resulted from Purbeck-Wealden recycling.

The carbon isotope ratios of limestones and some fossil carbonates have been shown^{11,12} to be affected by the proportional contributions of carbon-13-deficient carbon from land plants. They therefore provide additional evidence for differentiating marine and freshwater carbonate rocks. However, one must recognize that isotopic criteria, as well as trace-element criteria, fail to provide a clear-cut separate category for sedimentary rocks formed in transitional variable-salinity environments¹³. In deltas, estuaries and marginal bays, spatial and temporal changes of the carbon-13 : carbon-12 ratio of bicarbonate, food web and carbonates, may result from short-term changes in rainfall or the patterns of bars and distributaries, as well as from long-term advances and retreats of the sea. In shallow bays with restricted connexions to the open ocean, there may be additional complications due to variable amounts and isotopic compositions of the organic matter¹⁴ and of the carbon dioxide from its local decomposition^{15,16}.

Possible misinterpretations are to be expected in the palaeontological records as well, for example, where mass mortality of organisms results from abrupt salinity change, or where mollusc shells are transported, broken or size-sorted due to a change from static to dynamic hydraulic conditions.

The foregoing qualifications apply to the isotopic data here presented and to comparisons with other criteria used for environmental interpretation. Probably one should resist the temptation to sub-divide ancient variable-salinity environments except where (a) sufficient samples have been analysed to show lateral variation, and (b) there is a concordance of several indexes of environment.

Isotopic data are presented in Table 1, and the carbon isotopic compositions are shown diagrammatically in Fig. 1, for a stratigraphic sequence of Purbeck-Wealden limestone samples from southern England.

The graph of $\delta^{13}\text{C}$ variation (Fig. 1) can be interpreted, with reservations, as mainly representing relative variations in the influence of marine and continental waters. Reservations are based chiefly on the observation^{13,16} that $\delta^{13}\text{C}$ of modern organic carbonates exhibits an imperfect correlation with salinity of the water. The correlation is reasonably good in most transitional environments, but does not extend to shallow supersaline bays¹³.

As expected from their palaeontology, the Purbeck-Wealden carbonates show wide variations in carbon-13 content. An interesting upward trend is suggested: each succeeding carbon-13 minimum (and presumed minimum of marine influence) is more negative than the preceding. Stratigraphical horizons of the carbon-13 minima correspond with the virtually exclusive dominance of *Hydrobia* and *Valvata* (sample S8102), *Neomiodon* (sample S8114), *Equisetites in situ* (sample S8119) and ostracods (sample S8127). *Neomiodon* occurs in beds exhibiting a wide range of $\delta^{13}\text{C}$ and presumed salinity (as inferred by Casey⁴⁰ and confirmed by Hudson⁴¹), and its diagnostic significance should be questioned.

Maxima of carbon-13 content (and of presumed marine influence) also suggest, though less clearly, a general upward decline. They occur in the basal

Purbeck (sample S8101), again in the range Cinder Bed-Broken Shell Limestone (consistent with the presence of *Liostrea* and marine ostracods²², and the conclusion of Walker⁷) and near the base of the Wadhurst Clay (samples S8109, S8110, S8111: bed almost exclusively of *Neomiodon*). Successively smaller carbon-13 maxima occur in the lower Weald Clay above the Horsham Stone (*Filosina* beds: S8120 and S8121) and in the upper Wealden Shales (sample S8126, with oysters (*Liostrea*?), echinoids, ?*Viviparus*). The figure from the basal Purbeck limestones is consistent with Brown's recent conclusion that some of the basal deposits are marine or supersaline²⁴.

As a basis for comparison with prior data from elsewhere, an index mark is shown at $\delta^{13}\text{C} = -2$ parts per thousand (Fig. 1), the approximate mid-point between the means of marine and freshwater limestones analysed by Keith and Weber¹². We do not intend an arbitrary division of our present samples at $\delta^{13}\text{C} = -2$ parts per thousand, nor recommend that limestones from transitional environments should be more finely classified on the basis of carbon isotope ratios.

The oxygen isotope ratios (Table 1) do not show a strong correlation with $\delta^{13}\text{C}$, and there appears to be no advantage in using the 'Z' index of environmental discrimination based on both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ (ref. 12). However, eight of the present samples with $\delta^{13}\text{C}$ greater than -2 parts per thousand have a mean $\delta^{18}\text{O}$ of -4.5 parts per thousand, whereas twenty-two samples with $\delta^{13}\text{C}$ less than -2 parts per thousand have a mean $\delta^{18}\text{O}$ of -6.7 parts per thousand. The original oxygen isotope record seems not to have been entirely destroyed by recrystallization.

We conclude that the new carbon isotope data: (1) confirm the complex variability of Purbeck-Wealden carbonate environments; (2) suggest an underlying tendency for carbon-13, and presumed salinity, to decline with time; (3) indicate horizons of possible maximum and minimum marine influence where more intensive palaeontological, petrological, sedimentological and geochemical work seems likely to be rewarding.

We thank John Kaufman for assistance with the isotopic analysis. The work was supported by

Fig. 1. Variation in carbon isotopic composition of carbonates from the Purbeck-Wealden of southern England. Formations not sampled: A.B., Ashdown Beds; L.T.W.S., Lower Tunbridge Wells Sand; U.T.W.S., Upper Tunbridge Wells Sand. Analyses: ●, bulk carbonate, ▲, separated fossil shells; m, near-marine fauna (oysters, echinoids) presumed indigenously; V, *Viviparus* dominant, presumed indigenously. Sample numbers: Reading prefixes (S81-, see Table 1) omitted for simplicity.

(a) Data are for calcitic shelly and calcitic sandy or silty limestones, except that figures in parentheses represent separated fossil shells. Sample treatment and analyses were made by standard procedures¹¹. Isotopic compositions are expressed, in the conventional δ notation, as differences (in parts per thousand) from the PDB carbon dioxide standard.

(b) Tentative sub-divisions of Weald Clay after Worssam, B.C. (in litt.).

(c) 3 ft. from top. Carbonate almost entirely ostracod valves; little cement.

(d) Upper beds of Wealden Shales.

(e) Exact relations of these three horizons uncertain.

(f) Ref. 12, pp 1809-10.

(g) Identified by Dr. R. Casey.

(h) Carbonate (cement in quartzose sandy siltstone) probably penecontemporaneous because *Equisetites* tissue preserved^{19,20}.

(i) 30-40 ft. above base of Wadhurst Clay. Minor aragonite. Carbonate almost entirely *Neomiodon* valves; virtually no cement.

(j) Marine ostracods reported by Anderson²²; freshwater gastropods by Arkell²³.

(k) Walker²⁴ reported 405 p.p.m. "equivalent boron" in illite from the marine Cinder Bed. Our results (sample S8106) are consistent with his, and the overlying Broken Shell Limestone (sample S8107) seems to be dominantly marine. The same author also assigned a marine origin to the upper Durlston *Viviparus* beds on the basis of 390 p.p.m. equivalent boron in their illite fraction. Our results from the Purbeck-Wealden generally (see also Fig. 1, — V) do not suggest that *Viviparus* was marine.

(l) Identified by the late Dr. W. J. Arkell.

(m) Marine algae reported by Brown²⁵.

RETURN OF LEUCOCYTES TO THE BONE MARROW IN CHRONIC MYELOGENOUS LEUKAEMIA

By DR. JOHN H. MOXLEY* and PROF SEYMOUR PERRY

Medicine Branch

AND

PROF GEORGE H. WEISS and DR. MARVIN ZELEN

Biometry Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

IT is the purpose of this article to present evidence that immature leucocytes in the peripheral blood of patients with chronic myelocytic leukaemia (CML) may return to the bone marrow and mature. Our findings offer a possible explanation for the prolonged peripheral-blood disappearance time of CML leucocytes^{1,2}.

infused into the peripheral blood return to the bone marrow.

One other important possibility to consider for the presence of radioactivity in the bone marrow aspirate is peripheral blood contamination. In the evaluation of this possibility, the observed intensity of radioactivity in the aspirate can be written:

$$C_{\text{obs}} = p C_{\text{marrow}} + (1 - p) C_{\text{peripheral blood}}$$

where the C s refer to intensities and p is a parameter depending on the (volume) contamination and the ratio of densities of white blood cells per unit volume associated with the peripheral blood and marrow. Specifically it is:

$$p = \frac{1 - a}{1 - a + a \rho}$$

where a is the percentage contamination, and

$$\rho = \frac{\text{white blood cell density in peripheral blood}}{\text{white blood cell density in marrow}}$$

Measurements on the white blood cells in both the peripheral blood and marrow resulted in values of $\rho = 2/7$ and $1/5$ for patients A. S. and E. R., respectively. Estimates of peripheral blood contamination of bone marrow aspirate are in the neighbourhood of $a = 20$ per cent⁴. Substituting the foregoing values of ρ with $a = 0.2$ in the formula for p gives $p = 0.93$ (A. S.) and $p = 0.95$ (E. R.). If one assumes no radioactivity in the marrow ($C_{\text{marrow}} = 0$), then $C_{\text{obs}} = 0.07 C_{\text{peripheral blood}}$ for A. S. and $C_{\text{obs}} = 0.05 C_{\text{peripheral blood}}$ for E. R. This means that we would expect the observed radioactivity in the aspirate to be 7 per cent (A. S.) and 5 per cent (E. R.) of that in the peripheral blood. Even if the contamination

Fig. 1. Patient E. R., 58 years old, N, ♀. Ph_1^+ CML relapse, *in vitro* labelling. ○—○, White blood cells; ●, marrow

We have investigated the leucocyte kinetics in CML using techniques of liquid scintillation counting and autoradiography following *in vitro* leucocyte labelling with tritiated thymidine. Two CML patients, Ph_1 chromosome positive, were leucophoresed and their leucocytes labelled *in vitro* with 4 mc. of tritiated thymidine (sp. act. 1.9 c./mmole). After excess radioactivity was removed by two washings with autologous cell-free plasma, the labelled leucocytes were re-infused. At time zero and at intervals after labelling 5 ml. of blood and 2 ml. of bone marrow aspirate were obtained and processed by a method previously described³. The isolated leucocytes were washed, counted, hydrolysed, and their radioactivity determined in a liquid scintillation spectrometer. Autoradiographs of the whole-blood samples and of the separated leucocytes were prepared in the usual manner using Kodak AR 10 stripping film. Four thousand cells were counted for each autoradiograph. Details of the methods used will be included in a later publication.

Results of the liquid scintillation counting are presented in Figs. 1 and 2. Leucocyte radioactivity was followed in both the peripheral blood and bone marrow for 120 h in each investigation. The radioactivity in the marrow strongly suggests that some of the *in vitro* labelled cells

Fig. 2. Patient A. S., 47 years old, W, ♂. Ph_1^+ CML relapse, *in vitro* labelling. ○—○, White blood cells; ●, marrow

* Present address: Peter Bent Brigham Hospital, Boston, Massachusetts.

were as much as 50 per cent, the observed aspirate radioactivity would be 22 per cent (A. S.) and 17 per cent (E. R.) of that in the peripheral blood. Therefore the observations in Figs. 1 and 2 cannot be accounted for by peripheral blood contamination.

Corresponding evidence of return of CML leucocytes to the bone marrow was found in analysis of the bone marrow autoradiographs from one of the two patients (E. R.) (Tables 1 and 2). Seven per cent of the leucocytes obtained in the marrow aspirate on day 3 were significantly labelled. The labelled cells included 32 metamyelocytes and 19 mature granulocytes. This finding suggests that cells not only return to the bone marrow but also, while there, a portion of them divide and mature.

It is highly unlikely that immature leucocytes are able to mature during the 1-h *in vitro* incubation period. Consequently, for the purposes of assessing the significance of the results in Tables 1 and 2, we have assumed that all grains overlying mature cells in Table 1 represent background labelling. We will now show that the labelled mature neutrophils found in the bone marrow (Table 2) cannot be accounted for by the re-infusion of these background labelled mature cells. For this calculation:

L = total number of re-infused labelled leucocytes;

N_{PB} = total number of leucocytes in the peripheral blood;

N_m = total number of leucocytes in bone marrow;

E_g = labelling index;

E = leucophoresis efficiency.

(The leucophoresis efficiency is defined as the ratio of total number of leucocytes extracted from a given amount of whole blood to the total number of leucocytes in the given amount of whole blood.) Since 150 out of 946 labelled cells were mature neutrophils labelled *in vitro* by background, an average of $150/946 L = 0.16 L$ mature labelled neutrophils would be infused. Assuming that all these labelled mature neutrophils return to the marrow, we would expect to find:

$$(4,000) (0.16 L) / N_m$$

labelled mature cells in a bone marrow autoradiograph where the number of cells counted is 4,000. The total number of re-infused labelled leucocytes from a sample of 1,000 ml. of whole blood is:

$$L = \frac{1,000}{5,000} (E) (E_g) (N_{PB})$$

where 5,000 ml. is taken as the blood volume. Consequently, the expected number of labelled mature neutrophils counted in a bone marrow autoradiograph can be written as:

$$(4,000) (0.16) (0.2) (E) (E_g) (N_{PB}/N_m)$$

Table 1. *In vitro* LABELLING OF CML LEUCOCYTES WITH ³HTDR* (PATIENT E. R.)

Cell type	No. of cells	Grain count			
		< 5	5-10	11-15	16-20 > 20
Segmented neutrophils	513	40	8		
Band neutrophils	365	24	2

Erythroid precursors	84				

Yoffey cites (N_{PB}/N_m) to be 0.01 for normal individuals⁵. Yankee has found values of E between 0.35 and 0.70 in 25 CML patients⁶. Taking E to be 0.50 and $N_{PB}/N_m = 0.01$, the expected number of mature labelled neutrophils on a bone marrow autoradiograph should be $0.64 E_g$. The proportion of labelled cells to total cells counted gives an $E_g = 946/4,000 = 0.24$. Thus we estimate the expected number of mature labelled neutrophils to be 0.15. We observed 51 labelled mature cells, which clearly is a highly significant result.

Since tritiated thymidine labels cells only during the DNA synthesis phase, the presence of labelled mature granulocytes in the bone marrow indicates that immature cells which took up the label *in vitro* must have undergone maturation. The absence of labelled erythroid precursors in the bone marrow aspirate supplies strong evidence that our observations were not influenced by the re-utilization of the tritiated thymidine.

These preliminary results from examination of two patients with acute myelogenous leukaemia (AML) indicate that leucocytes do not return to the bone marrow in this disease.

EFFECTS OF CYCLIC ADENOSINE MONOPHOSPHATE AND MELANOCYTE-STIMULATING HORMONE ON FROG SKIN *IN VITRO*

By DR. M. W. BITENSKY and S. R. BURSTEIN

Department of Medicine, New York University School of Medicine, New York

IN 1957 Sutherland and Rall¹ described the function of cyclic-AMP in the control of glycogenolysis, thus providing insight into one of the mechanisms of hormonal regulation of enzymatic activity. These investigators have since characterized the enzymes involved in the synthesis and degradation of cyclic-AMP as adenylyl cyclase and phosphodiesterase, respectively². Davoren and Sutherland found that adenylyl cyclase is located on the cell membrane in the pigeon erythrocyte³. Sutherland and Rall and other investigators have provided evidence to support the role of adenylyl cyclases as intermediaries in the action of ACTH⁴, TSH⁵, glucagon¹, and epinephrine¹. Each of

these hormones has been shown to stimulate selectively an adenylyl cyclase in its respective target organ. Furthermore, Orloff and Handler⁶ demonstrated that the effects of ADH on the toad urinary bladder could be mimicked by cyclic-AMP. Subsequent work has shown that ADH increases the levels of cyclic-AMP formed in homogenates prepared from dog kidney⁷. Mansour *et al.*⁸ have reported activation of adenylyl cyclase by serotonin in *Fasciola hepatica*, and Rizaack⁹ has demonstrated that a lipolytic activity in rat epididymal fat pads is stimulated by cyclic-AMP, as well as by epinephrine. Although cyclic-AMP has been shown to control glucose utilization through

its action on phosphorylase kinase and on phosphofructokinase, and to affect glycogen synthesis through its action on transglucosylase¹⁰, little is known about the manner in which cyclic-AMP regulates other types of cellular activities.

Sutherland and Rall and their co-workers have thus described a common mechanism of interaction between a certain class of hormones and their target tissues. Although adenylyl cyclase and cyclic-AMP are involved in all these systems, there is a high degree of specificity both in the activation of a specific adenylyl cyclase by its appropriate hormone and in the way that the differentiated target cell responds to increasing levels of cyclic-AMP.

Skin darkening in the frog has been demonstrated with methyl xanthines such as caffeine and theophylline^{11,12}. Since these reagents are known to inhibit competitively the hydrolysis of cyclic-AMP by phosphodiesterase¹³, it seemed reasonable to enquire whether MSH causes pigmentary changes in amphibian skin by increasing cellular levels of cyclic-AMP.

The effects of various concentrations of cyclic-AMP were determined on excised strips of frog skin. Since it is known that cell membranes are relatively impermeable to this cyclic nucleotide, it was necessary to use higher concentrations than are believed to be present intracellularly¹⁴.

Summer *Rana pipiens*, stored up to two weeks at 4° C, were used. Strips of dorsal skin relatively free from spots were mounted vertically in 4-ml. cuvettes on a polystyrene frame (Fig. 1). All test reagents were dissolved in modified Ringer's solution (110 mmoles NaCl, 2 mmoles CaCl₂, 2 mmoles NaHCO₃ and 2 ml. KCl).

The time required for the full expression of hormonally induced pigmentary changes in amphibian skin was 1-2 h. By using the Gilford spectrophotometer, it was possible to record pigmentary changes in four skin specimens simultaneously. Optical density measurements were recorded at 530 mμ using a chart speed of 0.25 in. per min with a full-scale deflexion set equal to 0.500 O.D. unit. This method is based on the assumption that the optical density of frog skin is a function of the skin area occluded by dispersed pigment granules¹⁵. In practice, the method proved to be sensitive and precise, and the recorded changes in optical density correlated well with gross and microscopic observations. In addition, the smoothness of the curves obtained indicated that the optical density measurements were made from the same portion of each specimen during the experimental period.

At the time the frogs were taken from the cold room, their skins were usually dark. Before each experiment,

Fig. 1. Strips of frog skin approximately 5 mm × 25 mm were mounted on a polystyrene frame with 4-0 surgical silk and inserted in a 4-ml. cuvette. Optical density was measured at room temperature in a Gilford spectrophotometer at 530 mμ.

Fig. 2. Changes in optical density of frog skin caused by 5'-AMP and cyclic-AMP. A, 1.0×10^{-3} M cyclic-AMP; B, 5.0×10^{-3} M cyclic-AMP; C, 3.0×10^{-3} M cyclic-AMP; D, 5.0×10^{-3} M 5'-AMP; E, Ringer's solution alone. Results for cyclic-AMP are expressed as fraction of total net change, data from a single representative experiment are shown. Results for 5'-AMP and Ringer's are expressed as change in optical density from time zero divided by average net change for seven experiments with cyclic-AMP.

skin specimens were rinsed with Ringer's solution and allowed to equilibrate at room temperature in the cuvette. The skins lightened slowly and, after about half an hour, reached a constant optical density. The Ringer's solution was then replaced by various experimental media.

Aminophylline, β -MSH and ACTH produced an increase in optical density, and the time required and the magnitude of the net change achieved depended on the nature and concentration of the compound tested (Table 1). The results obtained with various concentrations of cyclic-AMP are shown in Fig. 2. In order to compare results with different skin samples, the optical density readings during the experiments are expressed as fractions of total change.

Compound concentration	Maximal increase in O.D. at 530 mμ	Time required for maximal 40 D. (min)
Aminophylline 1.0×10^{-3} M	0.177	38
β -MSH 0.10 μg/ml.	0.442	104
ACTH 0.30 mg/ml	0.418	54
Cyclic-AMP 1.0×10^{-3} M	0.298	64
5.0×10^{-3} M	0.419	112
3.0×10^{-3} M	0.381	123

The data represent average values for three or more experiments.

Although the rate of darkening of the specimens was related to the concentration of cyclic-AMP, the final net increase in optical density was approximately the same for all effective concentrations of the cyclic nucleotide. The lowest concentration of cyclic-AMP which produced a significant response was 3.0×10^{-3} M. In contrast, 5'-AMP did not significantly alter the optical density of the specimen at all concentrations used. Neither 5'-AMP nor cyclic-AMP caused any change in the optical density of the non-pigmented abdominal skin.

The spotted skin pigmentation characteristic of *Rana pipiens* caused some variability in the fraction of the total area of skin capable of undergoing a maximal degree of colour change. The results were surprisingly reproducible, considering that the areas of skin observed were heterogeneous and that experiments were made comparing skin specimens from different frogs.

Although oxygenation of the medium or the presence of physiological concentrations of glucose increased the magnitude of the optical density changes, these factors did not alter the rate or the direction of the relative response.

ACTH, α -MSH and β -MSH have all been shown to induce skin darkening in the frog¹². The common heptapeptide sequence shared by ACTH and the MSHs is thought to be responsible for their skin-darkening properties. The heptapeptide and, indeed, a derived tetrapeptide residue¹³ produce darkening in amphibian skins, but at much higher concentrations than are required for the parent hormones. Oxytocin and ADH, on the other hand, do not darken amphibian skin, and they do not contain this amino-acid sequence¹³. Interaction between the melanocyte and the active hormone and hormonal fragments could thus depend on the adenylyl cyclase system. Such interaction would imply that the melanocyte adenylyl cyclase system has a specific means of recognizing this particular amino-acid sequence.

Lerner *et al.*¹² have found that acetylcholine causes lightening of amphibian skin. This same compound causes a decrease in the formation of cyclic-AMP in cardiac muscle¹⁷. Paradoxically, epinephrine and serotonin induce lightening of amphibian skin¹². Although epinephrine and serotonin can stimulate the formation of cyclic-AMP in some mammalian tissues², it is not known what effects these compounds have on frog melanocyte cyclic-AMP levels.

The demonstration of darkening with cyclic-AMP *in vitro* provides some evidence that the mediation of pigmentary changes in frog melanocytes could involve an adenylyl cyclase. Further investigations on the adenylyl cyclase of melanocytes are needed, however, in order to evaluate directly the effect of MSH on intracellular levels of cyclic AMP.

We thank Dr. Aaron B. Lerner for a generous gift of purified β -MSH. This work was supported by the New

York Research Council and by a U.S. Public Health Service departmental research grant.

- ¹⁵ The following equation is suggested to describe the relationship between the light which is incident on the frog skin and that transmitted through it:

$$\frac{I_t}{I_i} = 1 - (R + C) \quad (1)$$

I_i is the intensity of the incident light, I_t is the intensity of the transmitted light, R is the fraction of light absorbed by a variable pigment system, and C is the fraction of light not transmitted because of constant optical properties of the skin. R can be expressed in terms of the ratio of the total area blocked by opaque pigment particles, x , to the total area illuminated, A :

$$R = \frac{x}{A} \quad (2)$$

It can then be shown that:

$$A.O.D. = -\log \left(1 - \frac{Ax}{B} \right) \quad (3)$$

where $B = A - A_0 - x_0$ and x_0 is equal to the initial area covered by opaque pigment particles.

BIOSYNTHESIS OF 2-AMINOETHANEPHOSPHONIC ACID: A PHOSPHORAMIDIC ACID RE-ARRANGEMENT?

By DR. W. SEGAL

Department of Biochemistry, University of Western Australia, Nedlands, Western Australia

RECENT papers have reported the presence of free and bound 2-aminoethanephosphonic acid (AEP) in protozoa^{1,2} and the sea anemone³. This substance possesses a C-P bond and represents the first example of such a bond in biological materials, but hitherto there has been no published information or theory on the mode of biosynthesis of AEP.

Free, lipid-bound, and protein-bound² AEP have been found and evidence for a glycerol ester of AEP has been presented³. In ³²P₄-labelling experiments Rosenberg³ found that in *Tetrahymena* cells in log phase, the uptake of label was greatest in the lipid-bound AEP, least in the free AEP, and intermediate in the protein-bound AEP remaining after solvent extraction. These results are compatible with the assumption that the lipid-bound AEP is the precursor of the free and protein-bound AEP. There is abundant evidence^{4,5} that lipid-bound AEP occurs together with, and is closely related to, the phospholipids. Rouser *et al.*⁴ have described the isolation and characterization of ceramide aminoethanephosphonate—a deoxy analogue of sphingomyelin—from sea anemone lipid. Baer and Stanacev⁵ and, contemporaneously, Rosenthal and Pousada⁶ have synthesized AEP analogues of phosphatidyl ethanolamine. The properties of these compounds correspond so closely to those of the normal cephalins that it was suggested^{5,6} that AEP may occur in nature as a cephalin analogue.

The purpose of this article is to propose, on the basis of the published data³⁻⁶ and the properties of phospholipids, ribonucleic acids, and model compounds, that AEP (XI) is derived from phosphatidyl ethanolamine (I) by the following mechanism:

There are numerous examples of phosphate migration in the chemical and biochemical literature. Baer and Kates⁷ have shown that cholestyl α -glyceryl phosphate (XII)

undergoes acid and alkaline hydrolysis liberating choline and forming α - and β -glyceryl phosphates via an intermediate cyclic phosphate.

α - and β -glyceryl phosphates + choline

The alkaline hydrolysis of ribonucleic acid (for example, XIII) affords 2'- and 3'-mononucleotides (XV) and (XVI), explained by Brown and Todd⁸ in terms of a cyclic phosphate intermediate (XIV). Furthermore, cyclic nucleotides of the type (XIV) have been isolated from the ribonuclease digestion of ribonucleic acids⁹.

The feature that these substrates have in common is the presence of an α -glycol half-phosphate ester system. Todd¹⁰ has pointed out that the phosphate residue remains attached to the glycol moiety in ribonucleic acid hydrolysis, and this is also the case for cholesteryl α -glyceryl phosphate (XII) hydrolysis. In the case of α -glyceryl inositol phosphate there are two different α -glycol systems available and the products of alkaline hydrolysis are inositol and α - and β -glyceryl phosphates and glycerol and two isomeric inositol phosphates¹¹.

Phosphatidyl ethanolamine (I) represents the amino analogue of an α -glycol half-phosphate ester. By a similar mechanism to cyclic ester formation (nucleophilic attack) cyclic ester-amide (III) formation is postulated together with the release of free α : β diglyceride (II)—the phosphate retaining the glycol analogue as in the examples above. Again, as in cyclic ester cleavage, the ester-amide (III) is postulated to produce phosphoryl ethanolamine (IV) and the isomeric *N*-phosphoethanolamine (V). The presence of phosphatases may be a factor determining the survival of the P-N bond in (V) and it is noteworthy that the P-N bond occurs in biological material as *N*-phosphocreatine and *N*-phosphoarginine. The phosphoryl ethanolamine (IV) is available for conversion to phosphatidyl ethanolamine (I) through the intermediate cytidine diphosphoethanolamine and α : β -diglyceride¹². The *N*-phosphoethanolamine (V) may be considered an antimetabolite of phosphoryl ethanolamine (IV)—possessing similar constitution and geometry. The differences in solubility and melting behaviour of phosphatidyl ethanolamines and the corresponding lecithins¹³ indicate that the zwitter-ionic form of (IV) would be relatively unimportant at physiological pH and that the polarity of (IV) and (V) would be similar. (Note added in proof. A recent study of the infra-red spectra of phospholipids (Abramson, M. B., *et al.*, *J. Biol. Chem.*, 240, 2389; 1965) assigns an intramolecularly hydrogen-bonded structure—involving amino and hydroxyl groups—to phosphatidyl ethanolamine and phosphatidyl serine rather than the zwitter-ionic character of lecithin.) As such the enzymatic systems may be insufficiently discriminating and likewise convert

(V) to the phosphoramidic acid derivative (VI) isomeric with the cephalin (I).

The *N*-phosphoethanolamine portion of the compound (VI) bears a relationship to phosphoglyceric acid (see XIX). The latter is enzymatically dehydrated (enolase) to phosphoenolpyruvic acid. The postulated dehydration of (VI) to the *N*-vinyl phosphoramidic acid (VII) is analogous to the formation of phosphoenolpyruvic acid and generates a potential carbanion which becomes activated by the electromeric displacement (VII) \leftrightarrow (VIII).

A Stuart model of (VII) is such that the *P*-vinylamino grouping is planar and lies symmetrically between two of the phosphate oxygen atoms while the third oxygen lies in the *P*-vinylamino plane. Furthermore the methylene carbon is in close proximity to the electron-deficient phosphorus. The intramolecular re-arrangement of (VIII) is postulated to account for the C-P bond formation (IX) and involves nucleophilic attack by a carbanion and heterolysis of the P-N bond. In this regard, Gilman and Robinson¹⁴ have shown that triethyl phosphate undergoes nucleophilic attack by the phenyl carbanion of phenyl magnesium bromide affording esters of phenyl- and diphenyl-phosphonic acids. A further indication that the intramolecular re-arrangement of (VIII) to (IX) is feasible is derived from the work of Bunyan and Cadogan¹⁵, who readily obtained diazonium salt derivatives and phosphate ester from the *N*-nitroso-*N*-phenylphosphoramidate (XVII), postulating the intramolecular mechanism shown as follows:

This re-arrangement is highly analogous with that postulated for (VIII) \rightarrow (IX).

The remaining steps in the biosynthesis involve hydrogenation of the imino-compound (IX) to the 'phosphonolipid' (X) which is considered (from the data of Rosenberg² and Kittredge *et al.*³) to be the precursor of free AEP (XI) and of protein-bound AEP.

Since the proposed mechanism (I) \rightarrow (XI) was derived, my attention has been directed to the recent isolation of α -amino- β -phosphonopropionic acid (APP) (XIa) from *Zoanthus sociatus* and *Tetrahymena pyriformis*¹⁶. This metabolite (APP) bears the same relationship to AEP as serine bears to ethanolamine, and it is considered that APP biosynthesis follows an analogous course involving phosphatidyl serine (Ia) in place of phosphatidyl ethanolamine (I).

G = α Diacyl glyceryl

The dehydration of (VI) to (VII) was compared with the enolase-induced dehydration of phosphoglyceric acid (XIX) to phosphoenolpyruvic acid (XX). The proposed mechanism, applied to phosphatidyl serine (Ia), affords the intermediate (VIa), the structure of which is more closely related to phosphoglyceric acid (XIX) than the initially compared intermediate (VI). The co-occurrence of APP and AEP suggests that APP may indeed be a precursor of AEP, similar to the precursor relationships of serine and ethanolamine and phosphoserine and phosphoryl ethanolamine¹⁷. Such a relationship between APP and AEP, however, is in accord with the proposed mechanism of their biosyntheses. It is noteworthy that phosphoenolpyruvate (XX) by electromeric shifts similar to that postulated (VII \leftrightarrow VIII) leads to the carbanion (XXI) which fixes carbon dioxide forming oxaloacetate (XXII) and inosine triphosphate (ITP) in the presence of inosine diphosphate (IDP).

The apparent absence of an intramolecular re-arrangement in phosphoenolpyruvate (XXI) forming a C-P bond as in VIII \rightarrow IX is explained in terms of the relatively diminished positivity of the phosphorus atom due to the dissociation of the phosphate residue of XXI.

The formation of the C-P bond VII \rightarrow IX postulates the intramolecular re-arrangement of an enamine (VII) which is a nitrogenous analogue of phosphoenolpyruvic acid (XX). In this regard it is significant that Rutter¹⁸ has postulated a similar mechanism involving an enzyme-enamine complex to account for the action of class I aldolases. Rutter's mechanism involves an initial Schiff base formation (XXIII) and protonation and deprotonation to produce the enamine (XXIV). Electromeric displacement (similar to that postulated in AEP synthesis (VII)) and nucleophilic attack on the aldehyde group of a second substrate leads to aldol synthesis (XXV).

The exchange of one of the protons of the methylene carbon atom with those of the medium as shown in (XXIII) \rightleftharpoons (XXIV) and the invariable *trans* relationship

of the hydroxyl groups on the carbon atoms of the newly formed bond¹⁹ is explained by the formation of the enamine intermediate (XXIV).

IMMUNITY TO MALARIA: ANTIGENIC VARIATION IN CHRONIC INFECTIONS OF *Plasmodium knowlesi*

By DR. K. N. BROWN and I. N. BROWN

National Institute for Medical Research, Mill Hill, London, N.W.7

SOME parasitic protozoa can survive and multiply in host animals which show high levels of parasiticidal antibody developed as a result of infection¹⁻⁴. In trypanosomiasis, repeated parasitaemias in the presence of lytic antibodies are produced by a succession of antigenic variants. Each variant stimulates a specific trypanocidal antibody and at the same time remains unaffected by antibodies to other variants; more than twenty variants have been recorded from one strain⁵. In *Brucei* group trypanosomes, the variants appear to differ in the antigenic constitution of at least two groups of soluble proteins⁶⁻⁸.

There is indirect evidence that some antigenic variation can occur in rodent malaria⁹, but repeated antigenic changes, of an order which might account for chronic simian or human malaria, have not previously been demonstrated. Alternative explanations of chronicity in

malaria include the suggestions that the parasite is only poorly immunogenic, or that, being intracellular, it is not accessible to antibodies¹⁰. On the other hand, it is unlikely that such a complex foreign organism would be poor in antigens, and the intracellular schizonts at least are known to react with antibodies¹¹. These considerations suggest that frequent antigenic variation similar to that occurring in trypanosomes is the most likely explanation of chronic malaria. Using a parasite agglutination test¹¹, direct evidence has now been obtained for repeated antigenic variation in *Plasmodium knowlesi* infections of monkeys. These experiments, and some of their implications for the immunology of malaria, are summarized here; full details will be published elsewhere.

A syringe-passed derivative of the 'Nuri' strain of *P. knowlesi*¹² was used, which is highly virulent in rhesus monkeys (*Rhesus mulatta*); death occurs within 4-6 days

of patency, with up to 90 per cent of the erythrocytes infected. Sub-curative chemotherapy produces a chronic relapsing infection with parasitaemias rarely rising above 1 per cent. A frozen stabilate¹³ of this strain, designated K1, was isolated by freezing citrated blood of a monkey 6 days after infection. Stabilates of four relapses, K1A, K1B, K19 and K21, were also isolated. K1A and K1B were successive relapses occurring 10 and 21 days after sub-curative proguanil treatment of a K1-infected monkey. Stabilate K19 was collected from a monkey infected with K1A, cured with sulphadiazine when the infection was patent, and then reinfected with K1A. Reinfection produced without further drug treatment a series of spontaneously terminating parasitaemias, of which stabilate K19 was the fourth; it appeared 34 days after reinfection. Another stabilate (K21) was collected at the fourth patency in a second chronically infected monkey. When nearly all the stock of a stabilate had been used, a direct derivative was isolated by inoculating the stabilate into a monkey from which further blood samples were frozen down soon after patency. These secondary isolations were designated K1A2 and K1B2.

Antisera to parasites derived from specific stabilates were obtained from monkeys cured with sulphadiazine, or sulphadiazine plus proguanil, when the infection had become patent following inoculation of the stabilate; sera were taken before infection and 7-14 days after drug treatment. Serum samples were also collected at intervals from the chronically infected monkeys. All the sera were stored at -20° C and inactivated at 56° C before use.

For the agglutination test, schizont- or trophozoite-infected erythrocytes were separated by centrifugation from heavily parasitized blood taken 6-7 days after infection with a stabilate. Five-fold dilutions of the serum in diluent (1 per cent normal monkey serum in saline) were set out in W.H.O. haemagglutination trays, and equal volumes (0.4 ml.) of a saline suspension of either schizont- or trophozoite-infected cells containing approximately 4×10^7 cells per ml. were added to each well. The trays were incubated at 20°-22° C for at least 3 h and then examined macro- and microscopically for agglutination. One unit of antibody was arbitrarily taken as the maximum dilution producing agglutination; serum titres were recorded in units/ml.¹⁴

The results of testing schizont-infected erythrocytes against antisera to homologous and heterologous parasites are summarized in Table 1, which shows both the high specificity of the reaction produced by each relapse type, and the titre of agglutinins detected. The antigenic specificity of each relapse indicated by these results was further emphasized when K19-derived parasites, which had failed to react with the antisera to other relapses, were tested against sera from the chronically infected monkey from which it was isolated. Two serum samples taken during the infection, but before the K19 relapse, had no effect on K19 parasites at 1/50 dilution, although the first sample agglutinated K1A, and the second sample agglutinated both K1A and K1B, at titres greater than 1,250 units/ml. In contrast, K19 parasites were agglutin-

ated by serum collected 6 days after the isolation of K19 at a titre of 6,250, and by a sample collected 67 days later at 31,250 units/ml. A similar result was obtained with sera and the stabilate K21 obtained from the other chronically infected monkey, and these K21 parasites appeared to be antigenically related to K19 (Table 1).

Schizonts derived from K1A2 and K1B2 (secondary isolations of K1A and K1B) were not appreciably less specific than K1A and K1B, but parasites at the second monkey passage of K1A2 reacted with both K1A2 and K1B2 sera at high titre, indicating that an increase in antigenic heterogeneity had occurred with passage.

Later relapses in the chronically infected monkeys rarely showed more than one parasite per hundred erythrocytes. The stabilates (K19 and K21) derived from late relapses produced a lethal infection when inoculated into normal monkeys, indicating that the low parasitaemias in the chronically infected animals were due to immune suppression of the parasites and not to a loss of virulence by these later variants.

As judged by the titres of agglutinins detected in our tests, *P. knowlesi* and presumably, therefore, other species of malaria, are quite strongly immunogenic. Natural antibodies were not involved in these reactions, since sera collected before infection were without effect. In some instances, artificial dissociation of the parasites by anti-malarials may have enhanced the immune response, but comparable titres of agglutinins were also detected after the spontaneous disappearance of the K19 and K21 relapses. Parasites derived from one relapse stabilate agglutinated at high titres only with antisera obtained from monkeys infected with the same stabilate, but sera from monkeys cured of infection with parasites from other relapses had little or no effect. It is conceivable that the difference shown by the K1A and K1B stabilates (that is, of successive relapses) were drug-induced, but this cannot apply to the other relapses, so that the specificity of the reaction seems explicable only on the basis of antigenic variation analogous to that occurring in trypanosomes. Also, in trypanosomiasis, drug- and antibody-induced relapse variants are antigenically indistinguishable (K. N. B., unpublished results). Eaton has shown that trophozoite-infected erythrocytes are not agglutinated¹¹, and we have found this to be so with antisera from monkeys infected with both homologous and heterologous stabilates. In a comparison of schizont- and trophozoite-infected cells isolated at the same time from a K1-infected monkey, the schizont-infected cells gave titres of > 1,000 units/ml. for anti-K1 serum, but the trophozoite-infected cells were not agglutinated by this serum or by antiserum to any other relapse. The absence of agglutination with homologous antiserum implies either that the trophozoites and schizonts are antigenically different, or that the trophozoites, unlike the schizonts, are protected from antibody by the containing erythrocyte. In exoerythrocytic *P. gallinaceum* the host cell becomes progressively damaged as the parasite matures¹⁵, and similar damage by the mature schizont to erythrocytes may render the schizonts more accessible to antibodies.

Table 1. TITRES OF AGGLUTININS AGAINST SCHIZONT-INFECTED CELLS IN SERA FROM MONKEYS IMMUNIZED WITH *P. knowlesi*

Serum												
Immunized with stabilate		K1		K1A			K1B		K1B2		K19	K21

* Serum taken from chronically infected monkey after isolation of the stabilate.

So far, the present experiments have shown only relapse-specific agglutinins and not the protective antibodies of similar specificity which are implied by the relapsing nature of chronic malaria. The appearance of aberrant schizonts and the decrease in the proportion of mature to immature schizonts which occurs at crisis^{10,16} indicate the possible protective role of antibodies reacting with schizont-infected cells, but whether the cells are destroyed by lysis or by phagocytosis following agglutination or opsonization is not clear.

In our experiments, relapses in chronic infections usually produced low parasitaemias only, but when stabilates of these relapses were inoculated into normal 'non-immune' monkeys, virulent fatal infections followed. Thus, there appears to be another partially protective immune response transcending antigenic variation, although purely variant-specific antibodies are probably decisive in terminating each relapse. The nature of the more general immunity is not known but it seems to be effective against all relapse variants, and may be a response to antigens common to all variants (unpublished gel-diffusion experiments have shown that common antigens occur). Alternatively, an adjuvant action by parasite constituents¹⁷ may produce a non-specific heightening of the immune response. Some of the splenomegaly and liver and bone marrow changes characteristic of malaria^{10,18} are perhaps associated with an adjuvant action^{17,19}, although in one investigation malarious children of three years of age showed no better response to tetanus toxoid than controls²⁰; auto-immune destruction of erythrocytes may also play a part in reducing parasitaemias²¹.

Exoerythrocytic infection was unlikely to have occurred with our blood-induced *P. knowlesi* infections²², but in other species, for example, *P. vivax*, erythrocyte-infecting relapses may also arise from the exoerythrocytic pool²³. There may be separate and distinct immunity to the two phases, erythrocytic and exoerythrocytic²⁴, and the persistence of exoerythrocytic infection as in *P. vivax* may itself involve antigenic variation. In infections like *P. falciparum*, a variant-transcending immunity in both the liver and blood may limit the duration of the infection.

The implications of antigenic variation for trypanosomiasis have been discussed elsewhere⁶, and some of these possibilities may be applicable to malaria. Insect transmission has a stabilizing effect on antigenic variation in trypanosomes, as all variants generally return to a common parent type following development in the vector^{25,26}. The possible occurrence of this reversion in malaria is of considerable biological interest, particularly as this parasite is known to have a sexual stage in the vector, and it may also be important in the interpretation of epidemiological and immunological data. The fluorescent-antibody and haemagglutination tests^{27,28} are currently used in malaria epidemiology but these reactions are not species specific and probably normally measure 'common' antigens. Nevertheless, when human malaria parasites are used as a source of antigen, possible reactions with the 'variable' antigens should be taken into account.

Frequent antigenic variation by the parasite may also be a factor contributory to the persistent macroglobulinaemia which sometimes accompanies malaria²⁹, as each successive variant antigen is likely to stimulate the production of a new 19S antibody³⁰ to give the raised IgM levels observed during continuously patent infections and at each relapse; a similar macroglobulinaemia occurs in trypanosomiasis³¹.

The simultaneous occurrence of two levels of immunity, one specific for each relapse variant, and the other transcending antigenic variation and only partially inhibiting all relapses, may account for the inconsistent results that have been obtained by artificial immunization^{10,32}, where the possibility of antigen variability within the strain used has not been allowed for. The development of an anti-malarial vaccine, particularly against *P. falciparum*, now seems to depend on the following considerations: (a) the

successful *in vitro* cultivation of the human parasite as a source of dead antigen or of attenuated live material³³; (b) the absence of appreciable differences between strains; (c) the ability of humans to develop an immunity transcending antigenic variation. Geographically separated strains may not be as different as once thought³⁴, and human adults do develop reasonable immunity to *P. falciparum*³⁵. Children exposed to endemic malaria, however, show high parasitaemias up to 6–10 years of age, and this susceptibility may mean that resistance depends on an experience of a wide but finite range of antigenic variants occurring in one locality. Alternatively, children, unlike adults, are perhaps incapable of developing a generalized immunity effective against all variants. Children do appear to become blood-positive earlier than adults after prophylactic antimalarial treatment^{36,37}, and young rats infected with *P. berghei* relapse more frequently and with higher parasitaemias than older animals (I. N. B., unpublished results). Thus, the young of some hosts may be constitutionally incapable of developing a generalized immunity, and if this should prove to be so, immunization is unlikely to be effective. Much more evidence is needed on this point.

To summarize, frequent antigenic variation has been demonstrated in blood-induced *P. knowlesi* infections, which implies that it probably occurs in human malaria also. This variation can explain the chronicity of the disease and the inconsistent results obtained with artificial vaccines; it may possibly account for, or contribute to, the persistently raised IgM levels which accompany malaria. Some degree of immunity transcending antigenic variation also occurs, but its potential value as a possible basis for the development of a vaccine is uncertain.

A PHARMACOLOGICAL INVESTIGATION OF HUMAN ISOLATED ILEUM

By DR A. BENNETT

Department of Surgery, King's College Hospital Medical School, Denmark Hill, London, S.E.5

A PART from a report of the action of 5-HT on isolated strips of circular muscle from the human ileum¹, the *in vitro* pharmacology of this tissue has been little investigated. The experiments recorded here are a preliminary investigation of the pharmacology of the circular and longitudinal muscle of human isolated ileum.

Strips of muscle were cut from specimens resected at operation and in most instances the mucosa was removed. Some of the specimens were from mid-ileum but most were from terminal ileum; a few of the circular muscle strips were from the ileo-caecal junction. The preparations were suspended in an organ bath containing Krebs's solution at 37° C and movements of the muscle were recorded on a revolving smoked drum by a frontal writing lever. The load on the tissue was usually 1 g. The details of the method and the drugs used were as described by Bucknell and Whitney² in their examination of human isolated taenia coli.

Most preparations exhibited moderate spontaneous activity throughout the experiment. Acetylcholine (0.01–0.5 µg/ml.) caused a contraction in each of the 21 experiments on circular muscle and in each of the 15 experiments on longitudinal muscle. This contraction

was either unaffected (Fig. 1) by hexamethonium (20–50 µg/ml.) or was occasionally reduced a little; the contraction was prevented by hyoscine (20–200 ng/ml.) and potentiated by eserine (0.3–1 µg/ml.). These results indicate that acetylcholine acts on muscarinic receptors and that none or only a little of its effect at these concentrations is due to stimulation of parasympathetic ganglia.

The sympathomimetic amines phenylephrine, nor-adrenaline, adrenaline and isoprenaline relaxed both the circular and longitudinal muscle strips (including those from the ileo-caecal junction), and inhibited spontaneous activity in each of seventeen experiments. In five of these, the muscle 'tone' was not high enough to show a relaxation, and the inhibitory effects were demonstrated by a reduction in the response to acetylcholine. In seven experiments, the α -receptor antagonist 'Hydergine' (1 µg/ml.) prevented the relaxation caused by phenylephrine but not that caused by isoprenaline; the β -receptor antagonist pronethalol (10 µg/ml.) prevented the relaxation caused by isoprenaline but not by phenylephrine (Fig. 2). The simultaneous presence of both antagonists prevented the relaxation produced by any of the sympathomimetic amines. As phenylephrine acts mainly on α -adrenergic

Fig. 1. The effects of hexamethonium (C6), hyoscine (Hyo) and methysergide (Meth) on the responses of a circular muscle strip of ileum to DMPP (D; 10 µg/ml.), acetylcholine (A; 20 ng/ml.) and 5-hydroxytryptamine (HT; 20 ng/ml.). Hexamethonium blocks DMPP but acetylcholine and 5-HT are unaffected. Hyoscine blocks acetylcholine but 5-HT is unaffected. Methysergide blocks 5-HT. Time-signal 1 min.

Fig. 2. The effects of 'Hydergine' and pronethalol on the relaxations produced by phenylephrine (Ph, 17 $\mu\text{g}/\text{ml}$.) and isoprenaline (Iso; 0.7 $\mu\text{g}/\text{ml}$.) 'Hydergine' blocks phenylephrine but not isoprenaline. Pronethalol blocks the effect of isoprenaline. Time-signal 1 min

receptors, and isoprenaline acts mainly on β -adrenergic receptors^{3,4}, these results indicate that both α - and β -adrenergic receptors are present in human ileum and that stimulation of either produces a relaxation. Similar results have been obtained with human colon² and jejunum⁵. Some investigators have found that in laboratory animals adrenaline contracts the ileocolic sphincter^{6,7} and terminal ileum⁸. The opposite findings in the present experiments that the circular muscle strips from the region of the human ileocolic sphincter were relaxed by sympathomimetic amines agrees with the *in vivo* observation⁹ on the ileocolic sphincter of a patient.

The ganglion stimulant DMPP (20–40 $\mu\text{g}/\text{ml}$.) was used in fourteen experiments on circular muscle strips and in thirteen experiments on longitudinal muscle strips. In every experiment on the circular muscle strips, including those from the region of the ileo-caecal sphincter, DMPP produced a relaxation; in one experiment this relaxation was followed by a contraction and in another experiment the first dose of DMPP caused a contraction, the second dose caused a relaxation followed by a small contraction, and thereafter DMPP only relaxed the tissue. Hexamethonium (20–40 $\mu\text{g}/\text{ml}$.) was used in eight of the fourteen experiments (Fig. 1) and blocked the response to DMPP in every case. In the presence of pronethalol (10 $\mu\text{g}/\text{ml}$.) or eserine (1 $\mu\text{g}/\text{ml}$.) DMPP caused a contraction. The effects of DMPP on the longitudinal muscle strips were less consistent. There was a relaxation in six experiments, a contraction in four experiments and no effect in one experiment. In the remaining three instances, the longitudinal strips were initially relaxed by DMPP, but as the experiment continued, DMPP produced only a contraction in one experiment, and produced a small relaxation followed by a larger contraction in two others. Hexamethonium (20–40 $\mu\text{g}/\text{ml}$.) prevented both the relaxant and contractile effect of DMPP. Hyoscine (0.1 $\mu\text{g}/\text{ml}$.) inhibited the contractile effect of DMPP and in one experiment converted it into a relaxant effect, while in other experiments 'Hydergine' (1 $\mu\text{g}/\text{ml}$.) and eserine (0.5 $\mu\text{g}/\text{ml}$.) converted the relaxation into a contraction.

Since adrenergic receptor blockade inhibited the relaxant effect of DMPP, and hyoscine abolished its contractile effect, it appears that DMPP can release both an adrenaline-like substance and acetylcholine. The finding that hexamethonium blocked the contractile effect of DMPP indicates that DMPP stimulates parasympathetic ganglia in the wall of the ileum. On the other hand, the possi-

bility that DMPP relaxes the ileum by acting on sympathetic ganglia conflicts with the general view that there are no sympathetic ganglia in the bowel wall. It is possible that the relaxant effect of DMPP is due to an action on sympathetic nerve endings, or on stores of adrenaline-like substances, or on inhibitory nerves in the intrinsic nerve plexuses.

Fig. 3. The effects of hexamethonium (C6), hyoscine (Hyo) and mepyramine (Mep) on the biphasic response to histamine. Hexamethonium and hyoscine have no effect but mepyramine blocks the relaxant and the contractile action of histamine. Time-signal 1 min

Human jejunum⁵ is usually contracted by DMPP, the ileum is usually relaxed, and the colon² always relaxed by DMPP. It appears, therefore, that this drug has a greater tendency to produce a relaxation in the more distal parts of the bowel.

Histamine (0.3–4 μ g/ml.) caused either a relaxation (twelve experiments) or a contraction (seven experiments) of strips of circular and longitudinal muscle; it had a biphasic effect in three instances and had no effect (0.4–2 μ g/ml.) in another. Both the relaxant and the contractile responses were unaffected by hexamethonium (20–40 μ g/ml.; Fig. 3) but were blocked by mepyramine (5–100 ng/ml.). Sympathetic receptor blockade did not affect the relaxation produced by histamine, and its contractile effect was not altered by hyoscine in doses which abolished the response to acetylcholine. Histamine, therefore, appears to have only a direct action on the longitudinal and circular muscle. This contrasts with the finding in guinea-pig ileum¹⁰ that histamine has a direct action on the longitudinal muscle but has an indirect action on the circular muscle.

5-Hydroxytryptamine (0.01–1 μ g/ml.) contracted both the circular and longitudinal muscle strips in each of twenty-four experiments. The contractions were prevented by methysergide (0.1 μ g/ml.; seven experiments) but were unaffected by hexamethonium (10–50 μ g/ml.; five experiments), hyoscine (0.1–1 μ g/ml.; seven experi-

ments) or mepyramine (0.1–0.2 μ g/ml.; four experiments) in doses which abolished the responses to DMPP, acetylcholine and histamine, respectively (Fig. 1). Fishlock¹ found that lysergic acid diethylamide completely blocked the effect of 5-HT on human ileum, and that hexamethonium and hyoscine partly blocked the effect. He concluded that 5-HT had both an indirect action (that is, through nerves) and a direct action on the tissue. Since lysergic acid diethylamide¹¹ and methysergide¹² have no effect on the indirect action of 5-HT, and since, in the experiments recorded here, hexamethonium and hyoscine did not affect the response to 5-HT, it appears that 5-HT acts directly on human ileal muscle.

I thank the many surgeons from this and other hospitals for their co-operation in making available the specimens of ileum.

CENTRAL STIMULANT PROPERTIES OF COMPOUNDS WITH PERIPHERAL MUSCARINIC PROPERTIES

By G. B. LESLIE

Research Laboratories, May and Baker Ltd., Dagenham, Essex

MOST drugs with an excitatory or stimulant action on the central nervous system (other than convulsants) have peripheral actions on adrenergic mechanisms. Imipramine-like anti-depressants and cocaine enhance the contractions of the cat nictitating membrane in response to noradrenaline or electrical stimulation of the pre-ganglionic sympathetic nerve¹. Monoamine oxidase inhibitors potentiate the actions of some sympathomimetic amines and cause an increase in the amounts of amines found in the tissues. Amphetamine has sympathomimetic actions. It was suggested by Rothballer² that a central adrenergic mechanism may be involved in the stimulant actions of these drugs. We know of few reports of central stimulant activity of compounds with peripheral muscarinic properties. Borison³ observed that pilocarpine administered into the cerebral ventricles of cats occasionally caused a rage reaction characterized by pilo-erection, hissing and unsheathing of the claws. A similar response to intraperitoneal injection of pilocarpine was reported by Zablocka and Esplin⁴. Another muscarinic compound, tremorine, was shown by Baker, Hosko, Rutt and McGrath⁵ to produce a similar state of rage, and George, Haslett and Jenden⁶ observed this following administration of oxotremorine, a metabolite of tremorine. Sabelli and Toman⁷ produced rage in cats with tremorine, arecoline, morphine and lysergic acid diethylamide.

We have examined the actions on the central nervous system of a number of drugs with muscarinic properties. The drugs examined were oxotremorine, pilocarpine, arecoline, carbachol and acetylcholine, which are known to cause bradycardia, hypotension, increased intestinal tonus, salivation and sweating, and are antagonized by atropinic drugs. These compounds were found to have marked central action of a stimulant nature.

The activity of these muscarinic drugs has been compared with that of several standard drugs in four tests for central nervous system stimulation. The tests used

were: (1) production of rage-like states in the cat; (2) behavioural changes in week-old chicks; (3) reversal of reserpine-induced sedation in the rabbit; (4) reversal of chlorpromazine-induced sedation in the rabbit.

(1) *Production of rage in the cat.* Drugs were injected into the cephalic vein or into the cerebral ventricles via an implanted cannula as described by Feldberg and Sherwood⁸. Cats were premedicated with a quaternary derivative of atropine (methyl bromide salt, 1 mg/kg) to prevent peripheral muscarinic effects, or with hyoscine hydrobromide (1 mg/kg) or ethopropazine (10 mg/kg) to determine whether the rage effect was mediated by a central cholinergic mechanism.

The cats were judged by two independent observers for the presence of rage characterized by pilo-erection, unsheathing of the claws, hissing, spitting, growling, crouching, flattening of the ears and attacking other cats or a moving object introduced into the cage. The results are summarized in Table 1. A number of muscarinic agents caused rage when administered intravenously. Rage was produced with physostigmine only at doses

Table 1. ACTIVITY OF SOME MUSCARINIC AND OTHER DRUGS IN PRODUCING RAGE IN CATS

Minimal dose (mg/kg intravenous) producing rage in cats premedicated 1 h previously with either atropine methylbromide, hyoscine hydrobromide or ethopropazine
Figures in parentheses refer to doses producing rage when injected into cerebral ventricles

Drug	Atropine methylbromide 1 mg/kg (i.p.)	Hyoscine hydrobromide 1 mg/kg (i.p.)	Ethopropazine 10 mg/kg (i.p.)
Morphine	10	10	10
Arecoline	0.2	>10	>10
Oxotremorine	0.1 (0.02)	>10 (>0.08)	>1.0
Pilocarpine	25	>200	>200
Physostigmine	0.1	>0.8	
Prostigmine	>0.4		
Acetylcholine	0.25 (>0.3)		
Carbachol	>0.25 (0.005)		
Nicotine	>1.0 (>0.02)		
Dimethylphenyl- piperazinium	>0.1		

which caused convulsions after the rage. When administered into the cerebral ventricle, carbachol caused a rage response, but acetylcholine and nicotine did not. Acetylcholine caused convulsions and loss of consciousness. Nicotine caused vomiting and twitching of the ears.

Rage produced by muscarinic drugs in the cerebral ventricles was preceded by tremors and ear-twitching and was followed by stupor.

Rage produced by muscarinic agents was similar to that caused by morphine, but unlike that produced by morphine it was prevented by premedication with hyoscine or ethopropazine. A further difference in the rage state was that cats treated with muscarinic rage-producing drugs would attack one another and any moving object. Morphine-treated cats made little attempt to bite or attack. Cats treated with muscarinic drugs also appeared hallucinated and more ataxic.

(2) *Behavioural effects in week-old chicks.* Since chicks at one week old have no effective blood-brain barrier⁹, it is possible to observe the central actions of compounds which do not normally reach the brain when injected intravenously. The effects of a number of muscarinic and other drugs are shown in Table 2. The drugs were injected in warm saline solution into the jugular vein. Arecoline, pilocarpine, oxotremorine and physostigmine produced a behavioural response similar to that observed by Key and Marley¹⁰ with amphetamine and methylphenidate—spreading of the wings, raising the head, feather erection, increased cheeping and increased ambulation followed by ataxia. Unlike amphetamine, the action of the muscarinic stimulant drugs were completely antagonized by hyoscine, ethopropazine and other atropinic drugs. Arecoline caused sedation in chicks premedicated with hyoscine.

Table 2. BEHAVIOURAL EFFECTS OF SOME MUSCARINIC AND OTHER DRUGS IN THE WEEK-OLD CHICK

Figures in parentheses refer to activity after premedication with hyoscine (1 mg/kg)

Drug	Groups of 5 chicks used at each dose-level	
	Dose (mg/kg i.v.) producing stimulation in 50% of animals	Dose (mg/kg i.v.) producing sedation in 50% of animals
Amphetamine	0.5 (0.5)	—
Adrenaline	> 1.0	0.02 (0.02)
Arecoline	0.05 (> 0.25)	> 0.1 (0.05)
Oxotremorine	0.025 (> 0.05)	> 0.1 (> 0.1)
Pilocarpine	25 (> 100)	> 100 (> 100)
Physostigmine	> 1.0 (> 1.0)	0.25 (0.25)
Prostigmine	> 1.0 (> 1.0)	0.20 (0.20)
Acetylcholine	> 1.0	0.8
Carbachol	> 0.2	0.05
Nicotine	> 1.0	0.025
Dimethylphenyl- piperazinium	> 0.025	0.0125

Acetylcholine, carbachol, nicotine and prostigmine caused no excitatory effects but produced sedative behaviour similar to that described by Key and Marley with adrenaline. The chicks became sedated, the head dropped, motor activity was much reduced and the eyes closed. These effects were not blocked by premedication with hyoscine nor with mecamlamine or pempidine.

(3 and 4) *Antagonism of drug-induced sedation in the rabbit.* The drugs were infused in dilute solution into the marginal ear veins of rabbits sedated with reserpine¹¹ or chlorpromazine¹². Central stimulants such as amphetamine, cocaine or lysergic acid diethylamide (LSD) and anti-depressant drugs such as imipramine and amitriptyline are able to reverse the sedation (as measured by reversal of ptosis) due to both chlorpromazine and reserpine. The activities of some muscarinic and other drugs in these tests are shown in Fig. 1. Arecoline, pilocarpine, oxotremorine and physostigmine were highly active in these tests, while nicotine, acetylcholine, carbachol and prostigmine were inactive. The activity of the active muscarinic drugs was abolished by premedication with hyoscine. That of amphetamine and LSD was not significantly altered by hyoscine.

The results obtained in our experiments indicate the presence of excitatory mechanisms in the central nervous

Fig. 1. Activity of some muscarinic and other drugs in reversing reserpine- and chlorpromazine-induced ptosis in the rabbit. White, activity after premedication with atropine methyl bromide (5 mg/kg); hatched, activity after premedication with hyoscine hydrobromide (1 mg/kg). C, Activity against chlorpromazine, R, activity against reserpine

system which are stimulated by muscarinic drugs. It is probable that the three actions we have investigated—rage in the cat, stimulation in the chick and reversal of drug-induced sedation in the rabbit—have quite different mechanisms of action.

The rage response elicited in cats by muscarinic drugs resembles that caused by electrical stimulation of the hypothalamus, described by Nakao¹³ and by Wasman and Flynn¹⁴, and it is possible that hypothalamic rage is mediated through a muscarinic mechanism and that central stimulation and rage caused by intravenous injection of oxotremorine, pilocarpine and arecoline are due to an action of these agents on the hypothalamus. A similar site of action could be postulated for the effects produced by carbachol injected into the cerebral ventricles. All these drugs were specifically blocked by non-quaternary atropine agents. It is surprising that acetylcholine did not cause rage when injected into the cerebral ventricles, since physostigmine was able to do so when given intravenously. It may be that other cholinergic receptors in the central nervous system, which caused stupor, masked the effect on the hypothalamus. There is evidence for cholinergic mechanisms involved in sleep. George, Haslett and Jenden¹⁵ demonstrated that micro-injections of oxotremorine or carbachol into the reticular formation of the pons or caudal mesencephalon of the cat caused effects indistinguishable from physiological sleep.

The fact that some muscarinic agents cause sedation, while others cause stimulation, in the chick may be due to some drugs penetrating more easily to parts of the brain where inhibitory or excitatory mechanisms are present. It is of interest that while we were able to antagonize the excitant effects with atropinic drugs, we could not antagonize the sedative effects with atropine, nor were these sedative effects blocked by drugs antagonizing the nicotinic effects of acetylcholine, for example, mecamlamine, pempidine and hexamethonium.

Our results in rabbits confirm that an excitatory cholinergic mechanism is present also in this species. These stimulant properties were specifically blocked by atropinic drugs which reach the central nervous system. Some of these muscarinic compounds (oxotremorine, arecoline) showed a more potent central stimulant action than any other drugs we have tested in the rabbit. The discovery by Shute and Lewis¹⁶ of cholinergic innervation in the ascending reticular activating system of the rat

provides evidence of a possible site of action for this stimulant effect of muscarinic drugs.

REGIONAL CHANGES IN BRAIN SEROTONIN AFTER HEAD X-IRRADIATION AND ITS SIGNIFICANCE IN THE POTENTIATION OF BARBITURATE HYPNOSIS

By DR. V. NAIR

Neuropharmacology and Biochemistry Laboratories, Michael Reese Hospital Psychiatric Institute and Department of Pharmacology, Chicago Medical School

It has been shown earlier in rats that X-irradiation of the head at high doses reduces the susceptibility to seizure with maximal electroshock¹. It was also observed that the pharmacological actions of central nervous system drugs such as anticonvulsants² and barbiturates³ were enhanced in these head-X-irradiated animals. The faster onset of drug action after irradiation may be explained by the blood brain barrier permeability changes revealed in the above studies. With regard to the prolongation of drug action after irradiation, several factors, in theory, may be implicated. Some of these are: (1) sensitization of brain by irradiation; (2) an abscopal effect (inhibition) on drug-metabolizing enzymes; (3) interference with the transport of drug from within the brain to blood; (4) specific changes in the neuro-chemical transmitters, that is, on their relative balance and/or distribution within the brain. The first three as they affect the barbiturate hypnosis have been considered in another publication⁴. The work recorded here deals with the effects of cephalic X-irradiation on brain serotonin (5-hydroxytryptamine).

Previous investigators have examined the effects of total body X-irradiation on the serotonin content of brain and other tissues. Their findings differ widely. Royal *et al.*⁵ found that in mice, one week after exposure to 900 r. X-irradiation, serotonin levels in brain, lung, kidney, spleen and liver were reduced below that of non-irradiated controls. Melching *et al.*⁶, however, failed to detect a reduction in the serotonin content of brain, liver or spleen of mice killed up to 2 h after exposure to 810 r. whole-body X-irradiation. Ershoff and Gal⁷ found no significant difference in the brain serotonin content between X-irradiated, γ -irradiated and control rats. They exposed the rats to 900 r. total-body X-irradiation and examined the brain at six days' post-irradiation. However, Ershoff *et al.*⁸ afterwards detected a reduction in the serotonin content of the brain and small intestine of rats exposed to 450 or 900 r. at 1, 3 and 6 days' post-irradiation. Speck⁹ examined the effects of massive total body X-irradiation on rat brain serotonin and found a small decrease at 18 h after exposure to 4,500 r. and immediately after 9,000 r. followed by a return to normal values. Whole-body radiation studies with 900, 4,000, 8,000 and 12,000 r. were performed in rats by Randic and Supek¹⁰. Immediately after irradiation, serotonin content was determined. No change was found after doses of 900 and 4,000 r. However, after the higher doses of radiation, a significant increase in brain serotonin was noted. The details of their work were not available. Differences in radiation factors, time of examination and method of serotonin estimation may account for the divergence in results among these investigators.

In the work recorded here, a systematic investigation of brain serotonin changes were made at various predeter-

mined intervals after irradiation, until the animals reached the terminal stage. Since we were primarily interested in the effects of radiation on the central nervous system, irradiation was restricted to the cephalic region with the rest of the body shielded. We feel that for studying the effects of radiation on the central nervous system, total-body radiation is less suitable, in view of the varied effects of radiation on other organ systems and their interaction with the central nervous system, which complicates the interpretation of results. Serotonin was determined in the whole brain as well as in the hypothalamus and medulla.

Male Sprague-Dawley rats ranging in weight from 200 to 230 g were used in these investigations. The irradiation conditions were the same as described in an earlier publication¹¹. Rats received a single dose of 10,000 r. or 500 r. to the head at a dose-rate of 295 r./min. The radiation source was a 250-kV 30-m.amp GE 'Maxitron' X-ray machine (Argonne Cancer Hospital, University of Chicago). After irradiation, the rats were housed two in a cage in air-conditioned quarters. Rats exposed to the high dose radiation were examined at 1, 24, 48, 72, 96, 120, 144 or 168 h post-irradiation while those exposed to the low dose were examined at the 72-h interval. They were killed by decapitation, and the brain quickly removed (visible blood being removed by means of filter paper) and weighed. Serotonin was determined according to the method of Bogdanski *et al.*¹². For the determination of serotonin in the hypothalamus and medulla, brain removed from the decapitated head was frozen on a bed of dry ice in a refrigerated room (-10°C). The part of the brain anterior to the pons was sectioned free-hand with a razor blade and 1-2 mm thick coronal sections were obtained. Hypothalamus was dissected out from these sections and tissue from 3-4 brains was pooled for each experiment. For medulla, pooled tissue from 2 brains was adequate. The procedure for the determination of serotonin was the same as that for whole brain except that the tissue was always homogenized in 2 ml. of 0.1 N hydrochloric acid irrespective of the weight of the sample. Since there was a progressive weight loss in heat-irradiated animals³, it was pertinent to examine the serotonin changes in starved controls also. For this purpose, rats were deprived of food and water and their brain analysed at varying intervals.

The effect of X-irradiation on the serotonin content of whole brain is shown in Table 1. It is noteworthy that the amine level began to rise about 48 h post-irradiation, reached a peak value about 72-96 h and subsequently returned to normal value by 144 h post-irradiation. That this is a specific effect of irradiation unrelated to the weight loss or nutritional changes is suggested by the absence of any such increase in the brain amine following total food and water deprivation for 72 h. In fact, star-

Table 1. RAT BRAIN SEROTONIN CONTENT

Time of examination (h)	Control	X-irradiation (10,000 r)	Food and water deprivation	X-irradiation (500 r.)
1-2	0.55 ± 0.02 (34)	0.58 ± 0.02 (4)		
24	—	0.54 ± 0.03 (7)		
48	—	0.81 ± 0.04 (7)	0.54 ± 0.01 (6)	
72	—	*0.70 ± 0.04 (10)	†0.47 ± 0.03 (6)	‡0.47 ± 0.02 (5)
96	—	*0.68 ± 0.03 (8)		
120	—	0.48 ± 0.05 (3)	†0.71 ± 0.06 (7)	
144	—	0.62 ± 0.008 (2)	0.50 ± 0.01 (3)	
168	—	0.59 ± 0.02 (2)		

The values are expressed as $\mu\text{g/g}$ wet weight tissue \pm S.E. The number in parentheses refers to the number of animals.

‡ $P < 0.02$

Table 2. REGIONAL CHANGES IN SEROTONIN CONTENT OF RAT BRAIN

	Hypothalamus	Medulla
Control	1.98 ± 0.31 (7)	0.76 ± 0.07 (10)
X-irradiated (10,000 r.)		
48 h post-r.	2.15 ± 0.24 (5)	0.75 ± 0.13 (3)
72 h post-r.	2.07 ± 0.26 (5)	*1.01 ± 0.07 (8)
96 h post-r.	2.00 ± 0.41 (4)	0.82 ± 0.10 (6)

The values are expressed as $\mu\text{g/g}$ wet weight tissue \pm S.E. The number in parentheses refers to the number of experiments, each experiment being composed of 3-4 animals in the case of hypothalamus and 2 animals in the case of medulla.

* $P < 0.05$

vation produced a fall in brain serotonin at 72 h ($P < 0.05$) and a rise at 120 h ($P < 0.05$). The significance of this bimodal effect of starvation is not understood. In contrast to this divergence in serotonin changes, the pattern of weight loss was about the same in both the 10,000-r. X-irradiated and totally starved animals. In both these groups, body-weight decreased linearly and almost to the same extent with time³.

The results of regional investigations are summarized in Table 2. It is interesting that hypothalamus, the region normally richest in serotonin, showed no increase in the amine level at 72 h post-irradiation, while significant increase in serotonin was detected in the medulla at this radiation interval. It may be recalled here that enhancement of barbiturate hypnosis was also maximal at this irradiation interval in animals exposed to 10,000 r. of X-ray. For example, the duration of thiopental hypnosis was increased about five-fold in the high dose irradiated animals. That this was a specific central nervous system effect of irradiation, unrelated to dehydration, nutritional factors, or fall in temperature, was established by appropriate controls³. In animals exposed to low dose cephalic X-irradiation (500 r.), serotonin level of the brain decreased at 72 h post-irradiation ($P < 0.02$). In these animals, in contrast to the high-dose irradiated ones, the barbiturate effects were also decreased, as evidenced by the shorter duration of hypnosis. Even though the decrease in serotonin seems to be the same in both the starved and low-dose irradiation groups, again this does not appear to be related to the body-weight changes. The loss in weight resulting from complete starvation was about 4-5 times that accompanying 500 r. cephalic X-irradiation³. The demonstration of an association of serotonin and enhancement of barbiturate hypnosis, although not of sufficient evidence by itself to suggest a cause and effect relationship, certainly raise some questions regarding the functional role of serotonin.

It is known that the reticular activating system (RAS) is very sensitive to the depressant effects of barbiturates and other sedative hypnotics¹³. The inability to maintain wakefulness under barbiturate medication is attributed to its depressant effects on the RAS. Brain stem reticular formation contains both inhibitory and excitatory fibres, and it has been postulated that they are dispersed diffusely throughout the reticular activating system¹⁴. The distribution of serotonin in brain parallels that of norepinephrine and, like the latter, is present in high amounts in areas controlled by the RAS. On the basis of his work on the reticular activation produced by epinephrine and structurally similar compounds, Dell has favoured the concept of an adrenergic mechanism at the reticular level¹⁵. Monnier has considered that the high-voltage, slow-wave

activity resulting from low-dose serotonin and 5-hydroxytryptophan was due in part to reticular depression¹⁶. It has been suggested that these two amines may have opposing functional roles, norepinephrine by association with the excitatory fibres and serotonin by association with the inhibitory fibres¹⁴. Other hypotheses and evidences concerning the neurohumoral regulation of reticular activity have been presented in the excellent review article by Killam¹⁷.

Many investigators have reported the potentiation of barbiturate hypnosis by serotonin¹⁸. The potentiation of barbiturate hypnosis in head-irradiated rats and its association with increased brain serotonin-levels revealed in this study are consistent with the above observations. Particularly interesting is the finding that, although whole brain analysis of head-irradiated rats revealed an increase in serotonin content, no such increase was seen in the region normally richest in the amine, that is, the hypothalamus. A significant increase was, however, detected in the medulla. It has been noted that low doses of ionizing radiation produce increased activity of the RAS^{19,20}. On theoretical grounds, it is thus not unreasonable to expect additive effects with central nervous system stimulants whose action is mediated through the RAS and antagonistic effects with central nervous system depressants. Indeed, the decreased barbiturate effects noted by us in the low dose irradiated group support this belief. Furthermore, as might be expected, the serotonin content of the brain decreased in the low-dose irradiated animals. These findings, viewed together, appear to reinforce the possibility that serotonin has a functional role (possibly by its association with the inhibitory fibres of the RAS) in the regulation of wakefulness. Further investigations under different experimental conditions should reveal whether or not the phenomenon described here—association of medullary rise in serotonin and suppression of wakefulness—is a general one. These investigations also re-emphasize the importance of regional examination of the brain with due regard to its anatomical and functional heterogeneity in biochemical studies of the central nervous system.

This work was supported in part by a grant from the State of Illinois Mental Health Fund 1711. I thank the University of Chicago Argonne Cancer Hospital and the Department of Radiology for use of the radiation facilities and Mr. James Bland for his assistance with the radiation procedure. I also thank Messrs. D. Shah and S. Finer for technical help.

CATION PERMEABILITY OF PHOSPHOLIPID MODEL MEMBRANES: EFFECT OF NARCOTICS

By DR. A. D. BANGHAM, DR. M. M. STANDISH* and NIGEL MILLER

Agricultural Research Council Institute of Animal Physiology, Babraham, Cambridge

IT would appear that spontaneously formed liquid crystals of egg lecithin (phosphatidyl choline), when swollen in salt solutions, exhibit many of the ion and water diffusion properties of biological membranes¹. Thus, if the unit structure of the liquid crystal is accepted as being that of a bimolecular leaflet and the concentrically arranged leaflets are assumed to form closed surfaces, the diffusion rate of anions and water across the membranes is found to be several orders of magnitude greater than the diffusion rate of cations¹. Furthermore, the diffusion rate of cations is very significantly controlled by the sign and magnitude of the surface charge at the lipid/water interface. For example, there is a decrease of the diffusion rate of Na^+ and K^+ as the negative charge on the membrane is decreased—diminishing to zero for a positively charged membrane¹. In contrast, the diffusion rates of Cl^- and water appear to remain high irrespective of the surface charge. Although such membranes do not appear to distinguish between different cations, the diffusion rate of anions is, with certain exceptions, related to their hydrated ion radius¹ ($\text{Br}^- = \text{Cl}^- = \text{I}^- = \text{HCO}_3^- > \text{NO}_2^- > \text{F}^- > \text{HCO}_3^- > \text{H}_2\text{PO}_4^-$).

Evidence has also been presented² which indicates that membrane-active steroids can modify the diffusion rate of cations in such a model-membrane system in a direction which is compatible with the hypothesis that cell or cell-organelle (lysosomes) lysis is preceded by an increase in cation permeability. While these investigations give some encouragement to the idea that the model system is a valid one, it was felt that they should be tested more rigorously against compounds the interaction of which with biological membranes had been more quantitatively investigated. To this end, the effects of a variety of narcotic compounds have been investigated.

The two most common groups of compounds that produce narcosis in excitable cells are the organic solvents, for example the *n*-alkyl alcohols, chloroform and ether, and the local anaesthetics characterized by the presence of secondary or tertiary amino-groups or both. The precise mechanism of action is not known for either group, but for the purposes of this investigation, the thermodynamic treatment proposed by Ferguson³, Brink and Posternak⁴ and Clements and Wilson⁵ relating narcotic activity to a free energy of adsorption of the compounds to a lipid phase and the discussion on the mode of action of local anaesthetics by Ariens and Simonis⁶ will form the basis of the discussion in the present article.

Experimental details together with a description of the molecular structure of the phospholipid liquid-crystals have been given by Bangham, Standish and Watkins¹. In principle, a mixture of egg phosphatidyl choline and dicetylphosphoric acid (90:10 mole/mole) in chloroform was taken to dryness *in vacuo*, the dried lipids were then swollen in a small volume (1.0 ml./30 μmole lipid) of 0.145 M potassium chloride containing about 100 μc . of $^{42}\text{K}^+$ and the milky dispersion dialysed against isotonic, non-isotonic, lightly buffered (pH 7.0) potassium chloride until the dialysate was free of $^{42}\text{K}^+$. Equal portions (0.6 ml.) of the dialysed dispersion were then pipetted into 0.6 ml. of the narcotic compounds already dissolved in 0.145 M potassium chloride (pH 7.0), and the mixture incubated for 30–90 min at 22° C. Finally, 1.0 ml. of the mixture was pipetted into a small, moistened dialysis bag which was then placed into 10.0 ml. of 0.145 M potassium chloride. A further dialysis was then carried

out for 30 min and the radioactivity of the final dialysate measured.

The organic solvents were tested at concentrations (*c*), which were varying fractions (*c/c₀*) of a standard state (*c₀*), that is, solvent saturated solutions of 0.145 M potassium chloride at 22° C. At the values of *c/c₀* used, the ideality of the solution is assumed and the *c/c₀* term is referred to as thermodynamic activity. Local anaesthetics were tested at various concentrations expressed as moles/l. Zeta potential measurements of the liquid crystals were carried out in an apparatus described by Bangham, Flemans, Heard and Seaman⁷.

Two important facts emerge from these investigations. First, the model membranes show a measurable response to all the compounds at or about their effective *in vivo* concentrations. Secondly, the cation diffusion behaviour is different for the two principal types of narcotic agent.

Organic Solvent Anaesthetics. At constant thermodynamic activity, the alcohols of the *n*-alkyl series clearly permit an increase in the diffusion rate of K^+ as the chain length decreases (Fig. 1). This result is completely in accord with a variety of well-documented *in vivo* systems tested against a similar series of alcohols. Indeed, if the ratios of the activities required for any one *in vivo* system are plotted against the ratios of the activities required to produce an equal diffusion rate in the present model system, the points are evenly distributed about the 1:1 correlation line. The maximum deviation corresponding to a $\Delta\Delta G$ of ~44 cal per mole on a total calculated free energy of ~230 cal per mole $-\text{CH}_2^-$. (Obtained from the activity values in Fig. 1 by calculating $\Delta G_{\text{heptanol}} - \Delta G_{\text{hexanol}}$, where ΔG is the free energy change required to produce equal K^+ diffusion rates.) Thus, the *n*-alkyl alcohol series exhibit a reasonable quantitative agreement between the model system and a constant end-point in

Table 1. PENETRATION OF EGG PHOSPHATIDYL CHOLINE MONOLAYERS BY VARIOUS ALCOHOLS AT AN INITIAL PRESSURE OF 30 DYNES/CM

Alcohol	Bulk concentration (moles/l.)	$\Delta\pi$	Area/alcohol molecule (\AA^2)	No. lipid molecules per alcohol in surface phase
$C_1 - C_8$ (Extrapolated)	e.g. CHCl_3		12,750	213 (0.5%)
C_1	0.0379	3.5	7,953	133
C_2	0.0135	4.2	4,884	81.4
C_3	0.0038	4.65	3,677	61.1
C_7	0.0014	6.1	1,996	33.2

Areas per alcohol molecule were calculated from the expression⁹

$$\frac{d\pi}{d \log_{10} c} = 2.303 \frac{A_1}{A_1 - A_\pi} kT\Gamma$$

where: $\frac{d\pi}{d \log_{10} c}$ is the gradient of the penetration pressures (π)—versus ($\log_{10} c$) curve at the particular concentration; A_1 is the initial area/egg phosphatidyl choline molecule in the constant area monolayer (\AA^2); A_π represents the area occupied by a phosphatidyl choline molecule in a pure phosphatidyl choline monolayer at a given pressure (π); k is the Boltzmann constant, T is the absolute temperature; Γ is the surface density of penetrant molecules (as molecules/ \AA^2).

an *in vivo* system. Such quantitative agreement appears to extend beyond *n*-alkyl alcohol series because, if one compares the diffusion rate of K^+ in the model system at the activities for butanol and propanol to that for ether and chloroform at an activity required to produce narcosis in a non-synaptic nerve fibre⁴, the agreement is also remarkably good (Fig. 1). It would not be unreasonable to conclude that narcosis induced by these types of compound could act by increasing the permeability to cations.

On the other hand, if the activity coefficients of a series of *n*-alkyl alcohols are similar in the hydrocarbon region of the phospholipid molecules, one might expect equal numbers of alcohol molecules to be present there at equal bulk phase activity. To test this explicitly for the membrane-forming lipids used in the model system, the pressure increase produced in a constant area monolayer, initially at 30 dynes/cm, was measured for a range of bulk concentrations of the different alcohols. The results, presented in Fig. 2, seem to support the idea that at equal thermodynamic activity an equal number of molecules of the *n*-alkyl alcohol series penetrate into the membrane. But the results already presented in Fig. 1 show that at equal thermodynamic activities the diffusion rate of K^+ increases as the chain length decreases; thus the shorter the chain length the more effective is the molecule. The conclusion extends the suggestion made by Haydon and Taylor⁸ that when the chain length of an

adsorbing molecule is small, say less than half the length of the lipid chain, the leaflet breaks up due to the formation of space in the hydrocarbon region above the short inserted chain. Their prediction, therefore, that in a homologous series of straight chain molecules the ratios of the aqueous concentrations producing break-up for members differing by one $-\text{CH}_2-$ would be:

$$\exp\left(\frac{-\Delta G_{\text{CH}_2}}{RT}\right): 1$$

is not entirely valid in the present system.

From the investigations of monolayer penetration (Fig. 2) it is possible to calculate⁹ thermodynamically the number of membrane molecules per narcotic molecule at aqueous concentrations capable of producing a state of narcosis in excitable cells (Table 1). Extrapolation of these values towards a chain length $n_{\text{CH}_2} = 1$, equivalent approximately to a small gas molecule such as CHCl_3 , would suggest that there would be as many as 213 phospholipid molecules per CHCl_3 (0.5 moles per cent CHCl_3)—a value in close agreement with that computed by Clements and Wilson⁵ from their investigations using inert gases.

Local Anaesthetics. Whereas there had been no obvious *a priori* reason why the model membrane system should demonstrate a measurable and parallel response to the organic solvent group of narcotics, the established relationship between the cation exchange diffusion rate and the sign and magnitude of the membrane/water interface¹ would predict a diminution of such rates if the local anaesthetic molecules were active in their cationic form. These compounds penetrate orientated lipid structures as shown by Skou¹⁰, and the results presented in Fig. 3 confirm and amplify the measurements of Bangham, Rees and Schotland¹¹ and show that all four of the local anaesthetic compounds—namely, nupercaine, tetracaine, cocaine and procaine—reduce the zeta potential of a negatively charged membrane system. Moreover, if one compares the ratios of the concentrations producing an equal reduction in zeta potential to the ratios of the concentrations producing a reversible nerve block¹⁰, the values are in reasonable agreement (Table 2). Too much emphasis should not be laid on this correlation, since the concentration ranges over which a nerve remains reversibly

Table 2

	Highest concentrations still producing reversible block (Skou) (mM)	Relative blocking potency	Concentrations for 5-mV reduction in zeta potential (μM)	Relative concentrations
Nupercaine	0.7	1.0	20.0	1.0
Tetracaine	2.5	3.57	100.0	5.0
Cocaine	44.0	63.0	891.0	44.5
Procaine	137.0	195.0	5,012.0	250.0

Fig. 4 Normalized leakage rates of $^{42}\text{K}^+$ out of egg phosphatidyl choline/15 per cent didecylphosphoric acid liquid crystals as a function of bulk local anaesthetic concentrations. ■, Nupercaine; ○, tetracaine; ◇, cocaine; □, procaine

blocked are considerable. It is encouraging, however, that the model membrane systems show significant reductions in zeta potential at the minimum blocking concentrations¹³.

As indicated earlier¹, the diffusion rate of cation is very significantly controlled by the sign and magnitude of the surface charge prevailing at the lipid/water interface. It was therefore with no surprise that we were able to establish a systematic reduction in the diffusion rate of cation out of the liquid crystals in the presence of the local anaesthetic compounds (Fig. 4).

That there is a poor quantitative agreement between the percentage reduction in cation leakage and the reduction of zeta potential for the two more potent anaesthetics, namely, nupercaine and tetracaine, may be ascribed to the experimental necessity of reacting a large number of lipid molecules with a limited small volume of anaesthetic solution. The trend throughout the series clearly suggests that the cation diffusion is reduced as the zeta potential becomes less negative. If this correlation reflects the mode

of action of local anaesthetics *in vivo* then it supports the view¹² that these compounds are primarily active in the ionized form. Two of the less potent compounds, however, have the further effect of increasing permeability at high concentrations, even though the zeta potentials continue to fall. It is tempting to suggest that this effect may be attributed to the presence of a higher proportion of un-ionized molecules since it was not observed when the system was studied at a lower pH.

Thus the model membrane system described broadly mimics the behaviour of biologically excitable membranes in their response to two chemically unrelated groups of reagents. Both groups manifest changes in cation permeability across a bimolecular lipid membrane but in opposite directions and explicable by different physical mechanisms.

Inherent in these investigations is the belief that narcosis represents a transient, reversible increase in membrane permeability to cation; higher concentrations resulting in a degree of permeability (Fig. 1) which the energy-driven pumps in biological membranes cannot keep up with. A Donnan redistribution of ions will develop due to the presence inside the cell or cell organelle of non-diffusible proteins, and the concomitant rise in osmotic pressure will cause swelling and rupture of the membrane^{3,13}.

MOLECULAR WEIGHT OF CHICK INTERFERON

By DR. D. C. BURKE and DR. J. ROSS

Department of Biological Chemistry, Marischal College, University of Aberdeen

THE molecular weight of interferon has been investigated by a number of workers. Burke¹ purified chick interferon, prepared in chick chorioallantoic membranes, twenty-fold to obtain material of molecular weight 63,000, which was homogeneous in the analytical ultracentrifuge. This figure for the molecular weight was consistent with that of less than 80,000 obtained by Porterfield *et al.*², based on the rate of diffusion of interferon through agar. However, several workers using chick interferon, prepared *in ovo* in chick embryo cells, found, by indirect methods, that the molecular weight of chick interferon was in the 13,000–45,000 range^{3–8}. Lampson *et al.*³ achieved 4,500-fold purification of interferon prepared *in ovo* to give a product of molecular weight 20,000–34,000 as determined in the ultracentrifuge. Thus, with two exceptions^{1,2} all the reported values for the molecular weight of interferon have been in the range 13,000–45,000. Since interferon is adsorbed by agar³, the value of less than 80,000 obtained by the diffusion method is of doubtful significance. The difference between our earlier results¹ and those of other workers^{4–8} could be due to the different methods of preparation of interferon that were used, that is, in chorioallantoic membranes rather than in chick embryo cells or *in ovo*. We have now found that the molecular weight of interferon prepared in chorioallantoic membranes is about 30,000, and that the preparation of molecular weight 63,000 is

heterogeneous, containing at least two other proteins apart from interferon.

Interferon was prepared in chorioallantoic membranes (CAM), and assayed by a plaque-inhibition method in chick embryo cells by methods previously described^{1,9}. Interferon was also prepared in chick embryo cells¹⁰, and *in ovo*³. Sucrose-gradient centrifugation was carried out by Dr. P. A. Charlwood, as previously described⁴. Gel-filtration was carried out, essentially by the method of Andrews¹¹, using a column 105 cm × 4 cm diameter, and 0.1M phosphate buffer, pH 7.7. A series of purified proteins were used to calibrate the column. The proteins in the eluant were estimated spectrophotometrically and, where possible, enzymatically. The elution volume of a protein was defined as the volume of eluate at which the maximum amount of protein was measured. In all cases, spectrophotometric and enzymatic assays gave identical values for the elution volume.

An estimate of the molecular weight of chick interferon was obtained by sucrose-gradient centrifugation of crude interferon. Concentrated CAM interferon was centrifuged in a sucrose gradient, together with radioactively labelled lysozyme and ovalbumin as markers⁴. The contents of each tube were then assayed for radioactivity, and for interferon activity by the plaque-inhibition assay. The results (Fig. 1) show that chick membrane interferon sediments at a rate between that of ovalbumin and lyso-

Fig. 1. The centrifugation of CAM-interferon in a sucrose gradient, using radioactively labelled lysozyme and ovalbumin as markers. Δ , Interferon titre, \square , lysozyme radioactivity; \circ , ovalbumin radioactivity

zyme, although closer to that of ovalbumin. Since Charwood¹² has shown that the rate of sedimentation of a protein in a sucrose gradient is a function of its sedimentation coefficient, these results suggest that chick membrane interferon has a sedimentation coefficient somewhat lower than that of ovalbumin (3.4 S). This corresponds to a molecular weight of about 30,000–40,000 for chick membrane interferon.

A second estimate of the molecular weight of chick interferon was obtained by gel filtration through 'Sephadex G-100'. The elution volumes of a series of proteins, with molecular weights in the range 20,000–65,000, were determined. When the elution volumes of the proteins were plotted against the logarithms of their molecular weights, a straight line was obtained (Fig. 2), although the points for two of the proteins did not lie on this straight line. One of these proteins, carboxypeptidase, was filtered using 10 per cent lithium chloride as eluant. When albumin and ovalbumin were filtered in 10 per cent lithium chloride, it was found that the elution volume of each protein was 100 ml. greater than the elution volume using 0.1M phosphate buffer, pH 7.7, as eluant. The elution volume of carboxypeptidase used in Fig. 2 was obtained by subtraction of 100 ml. from the elution volume found when 10 per cent lithium chloride was used as eluant, and is therefore an approximate figure. No explanation of the large elution volume of trypsin can be given, although there appears to be some doubt about its homogeneity¹³. Gel-filtration of concentrated CAM interferon, under identical conditions, gave an elution volume of 680–750 ml. These figures correspond to a molecular weight of 27,000–35,000. The recovery of biological activity was very low in early experiments, but by using larger amounts of interferon, working at 2° and adding 'Tween 80' to the eluting buffer, the recovery was raised to about 40 per cent. The biological activity of the eluate was unstable, presumably due to its low protein content. The product was still impure since it gave two precipitin lines on immuno-diffusion with an anti-interferon antiserum (see later). Samples of interferon prepared *in ovo*, or in chick embryo cells, were, after suitable concentration, filtered through the 'Sephadex' column. The elution volumes of 710–730 ml. and 710 ml., respectively, correspond to molecular weights of 29,000–31,000. Thus within the limits of this method, no differ-

Table 1. COMPARISON OF ELUTION VOLUMES IN 0.1M PHOSPHATE pH 7.7, AND IN 0.1 M CHLORIDE BUFFER, pH 2.0

Protein	Elution volume at pH 7.7 (ml.)	Elution volume at pH 2.0 (ml.)
Albumin	510	430
Ovalbumin	610	630
Pepsin	670	870

The elution volume of each protein was measured as described in the text.

ence was detected in the molecular weights of the interferon from the three sources.

The elution volumes of several proteins were also determined using a 0.1 M-chloride, pH 2.0, buffer as eluant (Table 1). The relationship between molecular weight and elution volume, determined for filtration at pH 7.7, was not applicable at pH 2.0. The elution volume of albumin was small at pH 2.0, indicating that the molecule was larger, and several authors¹⁴ have shown that albumin expands at low pH values. The elution volume of pepsin was smaller at pH 7.7 than at pH 2.0, and this is consistent with the elongated structure of pepsin at neutral pH values¹⁵. The elution volume of ovalbumin was virtually unchanged. The elution volume of CAM interferon was greater at pH 2.0 than at pH 7.7 and, by analogy with pepsin, this may be due to a more compact structure at pH 2.0.

The results show that the molecular weight of CAM interferon lies within the range 27,000–35,000, and are at variance with the molecular weight of 63,000 obtained for purified CAM interferon¹. It was therefore of interest to re-examine the product obtained by Burke's procedure. A 5-l. batch of crude CAM interferon was taken through this purification procedure, with results very similar to those previously described. The product, which had been purified about twenty-fold, gave a single band on starch-gel electrophoresis and a single symmetrical peak of protein when chromatographed on DEAE-cellulose at pH 5.8 with an increasing phosphate gradient. However, when the product was examined by agar-gel double-diffusion analysis or by immuno-electrophoresis using an anti-interferon rabbit serum, it was shown to be heterogeneous.

The antiserum had been prepared by repeated injection of rabbits with crude CAM interferon, and neutralized the biological activity of CAM interferon (J. Ross and D. C. Burke, unpublished results). It also contained antibodies to the other protein components of crude CAM interferon, including ovalbumin and albumin, immuno-electrophoresis showing that the serum reacted with seven of the ten components detectable in crude CAM interferon by starch-gel electrophoresis. Both agar-gel double-diffusion analysis and immuno-electrophoresis showed the presence of four components in the purified CAM interferon. One of these was identified as a trace of chick albumin (which could not be detected by starch-gel electrophoresis), and another was shown to be present in

Fig. 2. Relationship between the molecular weights of proteins and elution volumes from a column of 'Sephadex G-100', in 0.1M phosphate buffer, pH 7.7, plus 'Tween 80' (20 μ g/ml) at 2° C

control interferon preparations (that is, CAM interferon made as usual, but without exposure to ultra-violet-inactivated virus), and is therefore derived from the host cells. The other two components were only found in purified preparations, but it is not known if either was interferon. These components could not be resolved by starch-gel electrophoresis, a diffuse single band being obtained. The product obtained by Burke¹ is therefore impure, and the observed molecular weight of 63,000 must be that of the major component, which is not interferon.

We have attempted to estimate the purity of Burke's material by comparison of the specific activity of the different preparations. Our crude CAM material has a specific activity of about 10 M.R.C. interferon units/mg protein and the most purified preparation about 2×10^2 M.R.C. interferon units/mg. The best crude interferon that we have been able to prepare *in ovo* has a specific activity of 3 M.R.C. interferon units/mg protein, and this material has been purified 4,500-fold (ref. 3) and 6,500-fold (ref. 8), giving a specific activity for the products of 1.35×10^4 M.R.C. interferon units/mg and 1.95×10^4 M.R.C. interferon units/mg, respectively. Thus it would appear

that our earlier purified preparation¹ contained at most 1 per cent of pure interferon, and this amount of a second protein would not have been detected by the methods used.

ARGININE AND UREA BIOSYNTHESIS IN THE LAND PLANARIAN: ITS SIGNIFICANCE IN BIOCHEMICAL EVOLUTION

By PROF. JAMES W. CAMPBELL

Department of Biology, Rice University, Houston, Texas

THE most widely accepted theory of the origin of life on this planet is that of Oparin¹. According to this theory, the first living systems were heterotrophic and utilized the organic compounds then present in primaeval waters as their source of free energy. The acquisition of biosynthetic function—primitive autotrophy—came as these substrates were gradually depleted from the nutrient environment. During this period, catalysed biosynthetic reactions had a high positive survival value for those systems possessing them and selection led to the establishment of complete biosynthetic pathways². This sequence of events is implicit in the concept of biochemical unity in accounting for the occurrence of several major metabolic pathways in diverse living forms.

One such biosynthetic pathway which has received considerable attention in this connexion is that for the synthesis of the amino-acid arginine, a universal protein constituent which is especially abundant in some nucleoproteins. This pathway is present, in whole or part, in bacteria, blue-green and green algae, yeast, fungi, higher plants, and most major vertebrate classes. Besides being the source of a necessary protein constituent, the arginine pathway has additional significance in biochemical evolution in serving as the main route for ammonia detoxification in ureotelic vertebrates. Urea synthesis is only one step removed from that of arginine, and it has been suggested that ancestral vertebrates utilized this pre-existent pathway for ammonia detoxification during the invasion of the land³. The utilization of the arginine pathway for ureotelism required mainly a change in the nature of the carbamyl phosphate-forming enzyme which enabled it to function efficiently at low ammonia concentrations.

While this has been recognized as an important step in evolution for the vertebrates, the exploitation of the arginine pathway for ureotelism by invertebrates during their invasions of the land habitat has not previously been considered. This was due, perhaps, to the lack of documentation of this pathway in any extant invertebrate species. From a consideration of the theoretical aspects of the establishment of metabolism², there is little reason to suspect that the pathway would not occur among the

invertebrates. The alternative would be that the pathway was not continuous in its evolution; that is, that it arose in primitive cells, was not present during the long geological period of the invertebrates, and then reappeared in ancestral provertebrates. In this alternative, the selective pressures which brought about the redevelopment of the pathway would seem more obscure, since they would not at first appear to be nutritional ones. On the other hand, the presence of the arginine pathway, in whole or part, among the invertebrates is more in keeping with the general concepts of biochemical unity since it indicates that the pathway was continuous in its evolution.

Urea cycle enzymes are of common occurrence among terrestrial invertebrates. Arginase has long been known to occur in the land snail⁴, the earthworm⁵, insects⁶, and more recently along with ornithine transcarbamylase, in the land planarian⁷. All urea cycle enzymes have now been demonstrated in the earthworm^{8,9} and it has been shown in another report that they function *in vivo* to synthesize both protein arginine and excretory urea¹⁰. Except for carbamyl phosphate synthetase, all other urea cycle enzymes have also been demonstrated in the land snail¹¹, and the incorporation of bicarbonate-¹⁴C into citrulline¹², protein arginine¹³, and urea^{12,14} indicates that the pathway is complete. Its role in excretion or nutrition in the snail is not, however, as yet clear. Although arginase occurs in some insects, ornithine transcarbamylase apparently does not¹⁵, and arginine is required in the diet¹⁶. Insects thus seem to lack the capacity to synthesize citrulline although it can partially replace arginine in the diet¹⁶. In this respect, they occupy a similar position among the invertebrates to birds among the vertebrates¹⁷.

Because of the land planarian's unique phylogenetic position among the terrestrial invertebrate species, it was of considerable interest to examine it for the presence of the arginine pathway. The origin of the Metazoa is not agreed on, but some feel that primitive flatworms bear certain similarities to the hypothetical first metazoans¹⁸. In any event, the land planarian, although itself a specialized species, may well represent the first successful invasion of the land by animals. The present report of

the urea cycle in the land planarian indicates, first of all, that the arginine pathway was probably present in the most primitive invertebrates, thus supporting the idea that the pathway was continuous in its evolution from unicellular organisms through to the vertebrates. Secondly, it once again demonstrates the importance of the arginine pathway and the development of ureotelism in the invasion of the land by animals.

The land planarians were collected in a local greenhouse and were identified as *Bipalium kewense* on the basis of external characteristics and with reference to Hyman¹⁹. They were kept until their guts emptied and were washed in 0.017 per cent 'Zephrian chloride' (Wintthrop Laboratories trade mark for alkyl dimethylbenzylammonium chloride) to free the external surface of bacteria. They were not checked for symbionts such as pleuropneumonia-like organisms, and I have assumed that the metabolism measured is attributable to the flatworms. Arginine is rapidly degraded by pleuropneumonia-like organisms (PPLO)²⁰, and in infected cells arginine synthesis from bicarbonate apparently does not take place²¹. Urease activity, which is widely associated with bacteria²², could not be detected in *Bipalium*²³ and this suggests that contamination may not have been a factor. For incubation, the flatworms were placed on filter paper moistened with 0.004 per cent 'Zephrian chloride' in sterile 225-ml. Warburg vessels. The side arms contained 3 μ mole $\text{NaH}^{14}\text{CO}_3$ (20 μC , ^{14}C). The vessels were sealed and the $^{14}\text{CO}_2$ was liberated into the chamber by adding sulphuric acid into the side arm through a rubber seal. The worms were kept in the $^{14}\text{CO}_2$ atmosphere for 4–5 h at room temperature (23°–24° C) and were then homogenized in 9 vol. 5 per cent trichloroacetic acid (TCA). The homogenate was centrifuged and the supernatant fluid was collected. The residue was washed twice with TCA and these washings were combined with the supernatant fluid and stored at –20° C until analysed.

The incorporation of $^{14}\text{CO}_2$ into protein arginine, aspartic acid and glutamic acid is shown in Table 1. To isolate the protein amino-acids, the residue from the foregoing was washed three times with TCA, twice with hot TCA (kept in a water bath at 68° C), twice more with TCA, twice with ethanol, twice with hot 3:1 ethanol-ether (52° C), twice with 2:2:1 ethanol-ether-chloroform (52° C), and finally with anhydrous ether. The dried residue (an average of 126.5 mg/g fresh wt.) was suspended in 100 vol. constant-boiling, peroxide-free hydrochloric acid and was hydrolysed in a sealed tube for 20 h at 115° C. The hydrolysate was freed of hydrochloric acid *in vacuo* and was decolorized with 'Nortit-A'. The amino-acids in portions of the hydrolysate representing 1 mg protein were separated by two-dimensional chromatography on Whatman 3MM paper using 2-butanone-formic acid-water (75:15:10, by vol.) in the first dimension and 75 per cent (w/w) phenol in an ammoniacal atmosphere in the second. The radioactive compounds were located by autoradiography and were eluted from the paper with water. A portion of the eluate was plated on aluminium planchets for radioactivity measurements and another portion was used to determine the amount of amino-acid present. For arginine, a modified Sakaguchi method was used, and for aspartic and glutamic acids, the picryl sulphonic acid method²⁴. No correction was made for absolute recoveries: arginine made up 4.88 per cent of the protein when determined as Sakaguchi-positive material in the protein hydrolysate, and 4.26 per cent by the chromatographic method. With this method, incorporation of carbon-14 was detected only in those amino-acids listed in Table 1.

To isolate arginine from the protein hydrolysate, carrier arginine was added to that remaining after chromatography to give a total of 20 mg. The arginine was then precipitated as the difluoride which was recrystallized to constant specific radioactivity²⁵. The difluoride was

* Incorporation into protein from 1 g tissue during a 4.67 h incubation.

† No corrections were made for dilution due to non-radioactive metabolic CO_2 formed during the incubation.

Table 2. INCORPORATION OF $^{14}\text{CO}_2$ INTO FREE AMINO-ACIDS AND UREA OF *Bipalium*

Compound	Tissue content (μ mole/g)	Total incorporation (c.p.m./g)	Specific activity (c.p.m./ μ mole)	CO_2 incorporated (μ mole/24 h)
Alanine	5.6	54,520	9,692	87.1
Arginine	<0.1	806	~8,850	1.3
'Argininosuccinate compounds B + C'	~1.3	3,742	2,917	5.9
Aspartic acid	9.0	112,604	12,512	180.6
Citrulline	<0.1	17,730	~209,500	28.3
Glutamine	0.5	1,521	3,073	2.4
Glutamic acid	11.3	76,462	6,797	122.2
Glycine	0.5	1,080	2,087	1.7
Serine	1.0	1,512	1,493	2.4
Urea	6.0	161,577	26,896	258.2

In addition to the compounds listed above, two unidentified ones also contained radioactivity. One, a total of 2,410 c.p.m., and the other, 1,580 c.p.m.

decomposed with 'Dowex-2(Cl-)'. The guanidino-C was liberated by treating 17 mg of the isolated arginine with 10 mg arginase and 10 mg urease in 0.1 M *tris* sulphate, pH 7.8, containing 0.005 M cobalt sulphate for 4 h at 38° C. Acidification of this reaction mixture liberated the guanidino-C as $^{14}\text{CO}_2$, which was absorbed in sodium hydroxide and precipitated and counted as $\text{Ba}^{14}\text{CO}_3$. Of the total carbon-14 incorporated into arginine, 97.3 per cent was present in the guanidino-C. Ornithine was isolated from the reaction mixture with 'Dowex-50(H^+)' after the arginase-urease treatment and was recrystallized from 80 per cent ethanol. It contained 1.3 per cent of the incorporated carbon-14.

The incorporation of $^{14}\text{CO}_2$ into the free amino-acids and urea is shown in Table 2. These compounds were isolated from the combined TCA supernatant and wash solutions with 'Dowex-50(H^+)' and were separated by two-dimensional chromatography as already mentioned. The amino-acids other than arginine and citrulline were determined with picryl sulphonic acid. Arginine was determined with the Sakaguchi reaction and citrulline as described by Archibald²⁶. The latter two compounds were added as non-labelled carriers to the free amino-acid fraction and their estimation is based on difference plus recovery corrections. The compounds designated as 'argininosuccinate B and C' were chromatographically identical to the two compounds formed when authentic argininosuccinate was carried through the isolation procedure used for the amino-acids. They are probably the two cyclic forms identified by Westall²⁷ and designated by him as compounds B and C, although authentic samples of these were not available for comparison. The estimation of these compounds was with an L-ornithine standard. A portion of the isolated citrulline was arsenolysed with ornithine transcarbamylase¹² and the ureido-C was determined as $\text{Ba}^{14}\text{CO}_3$. This C contained 91 per cent of the incorporated carbon-14. Urea was determined as described by Archibald²⁸ and a portion was also decomposed with urease to determine the urea-C as $\text{Ba}^{14}\text{CO}_3$.

The pattern of incorporation of $^{14}\text{CO}_2$ into citrulline, arginine and urea shown by *Bipalium* has been found repeatedly to be due to the operation of the urea cycle in ureotelic vertebrates. In addition, both ornithine transcarbamylase and arginase occur in this land planarian⁷. Both enzymatic^{29,30} and isotope incorporation data^{30,31} are now available which indicate that arginine and urea are synthesized in all classes of flatworms by the Krebs-Henseleit ornithine-urea cycle. This extends the distribution of this pathway to at least two major invertebrate phyla, the Platyhelminthes and the Annelida, and indicates that it is indeed a primitive pathway which

has persisted in some species of most living groups, while having been lost, in whole or part, from others.

This work was supported by U.S. Public Health Service grant AI 05006. I thank the personnel of the Hans Peterson Nursery, Houston, Texas, for their help in collecting the flatworms.

CHLORAMPHENICOL-, DIHYDROSTREPTOMYCIN-, AND KANAMYCIN-INACTIVATING ENZYMES FROM MULTIPLE DRUG-RESISTANT *Escherichia coli* CARRYING EPISOME 'R'

By SUEHIKO OKAMOTO and YOSHIKI SUZUKI

Department of Chemistry and Laboratory of Radiation Research, National Institute of Health, Shinagawa-ku, Tokyo, Japan

IN our previous investigations¹, no drug resistance was observed in the cell-free amino-acid incorporation system from chloramphenicol- or tetracycline-resistant strains of *Escherichia coli*. The resistant strains examined in those investigations included chloramphenicol- or tetracycline-resistant strains selected by serial transfer on media containing the drugs (the *in vitro* developed chloramphenicol- or tetracycline-resistant strains) as well as a naturally occurring multiple drug resistant strain carrying episome 'R' (resistant to four drugs: chloramphenicol, tetracycline, dihydrostreptomycin and sulphanilamides).

Recently by a modification of our experimental conditions we obtained from the strain carrying 'R' a cell-free amino-acid incorporation system resistant to chloramphenicol and dihydrostreptomycin.

Further study revealed that components responsible for the cell-free resistance reside in the 100,000g supernatant fraction and not in the ribosomes. The resistance shown in cell-free systems was finally found to be due to drug inactivating enzymes in the 100,000g supernatant fraction. Inactivation of chloramphenicol requires acetyl-coenzyme A, while ATP is required for inactivation of dihydrostreptomycin. The absence of acetate ion in our previous systems clearly explains our failure to detect chloramphenicol resistance on the cell-free level.

A kanamycin inactivating enzyme was also found in the cell-free extract of another 'R' strain which is resistant to kanamycin as well as to the four drugs already mentioned. Acetyl-coenzyme A was shown to be a required co-factor in the system.

In this article, partial purification and some characterization of these drug inactivating enzymes will be reported.

Inactivation of the drugs by the extract of the 'R' strain. The bacterial strains used were: (1) *E. coli* K12 CS-2 (Skaar and Garen²) sensitive to all the drugs tested here; (2) *E. coli* K12 ('R-4'), a strain resistant to four drugs (chloramphenicol, dihydrostreptomycin, tetracycline and sulphanilamides) derived from K12 CS-2 by transmission of an 'R' factor ('R-4') from a naturally isolated drug resistant strain of *Shigella flexneri*³; (3) *E. coli* K12 ('R-5'), a five drug resistant derivative of K12 CS-2 obtained by transmission of an R factor ('R-5') from

another naturally isolated drug resistant strain of *Shigella sonnei*⁴ which was resistant to kanamycin in addition to the four drugs already mentioned. The concentrations of drugs required to produce 50 per cent inhibition of growth of K12 CS-2 in the peptone-glucose medium are 0.6 µg/ml. of chloramphenicol, 3.6 µg/ml. of tetracycline and 0.75 µg/ml. of dihydrostreptomycin, and 90, 25 and 10 µg/ml. for K12 ('R-4') and ('R-5'). The respective 50 per cent inhibition doses of kanamycin for K12 CS-2 and for K12 ('R-5') are about 1 µg and 10 µg/ml. Cells were grown in peptone-glucose medium with aeration to the late log phase (2-3 g of wet cells per litre); the culture was chilled rapidly by pouring on to crushed ice and gathered by centrifugation. Cells were washed and homogenized in an equal volume of 0.02 M *tris* buffer (pH 7.8) containing 0.01 M magnesium acetate, 0.06 M potassium chloride and 0.006 M 2-mercaptoethanol, and disrupted by passage through a French pressure cell. The disrupted suspension was centrifuged at 30,000g for 20 min. This supernatant was dialysed over-night and further fractionated into a supernatant fraction (100 S) and ribosomal fraction by two centrifugations at 100,000g for 90 min.

As already mentioned, the 100 S fraction of the 'R' strain causes cell-free resistance to chloramphenicol or dihydrostreptomycin, but incubation of the drugs with this fraction in the aforementioned buffer does not result in any significant inactivation of the drugs. Then, it was found that the drugs are inactivated when incubated in the complete system of amino-acid incorporation containing the 100 S from K12 ('R-4'). Further investigations on the necessary factors for drug inactivation revealed that chloramphenicol is inactivated by the 'R' 100 S to a limited extent in the presence of ATP; the 'R' D-C fraction (see as follows) freed from low molecular weight substances exhibited an absolute requirement for ATP, coenzyme A and acetate ion as shown in Table 1 (Exp. 1). Dihydrostreptomycin was found to be inactivated by the 'R' D-C fraction in the presence of ATP and Mg⁺⁺ (preferably with ATP generating system) (Table 2). The ATP cannot be replaced by ADP, AMP, GTP, CTP or UTP. Addition of coenzyme A produces

no significant stimulation of the reaction. Extracts from K12 *CS-2* elicited very little or no inactivation of the drugs under the same conditions (Table 3); this seems also to be the case in the *in vitro* developed chloramphenicol-resistant strain since it does not give a resistant cell-free amino-acid incorporation system.

In addition, the *D-C* fraction of K12 ('R-5') was shown to inactivate kanamycin, which was not observed in the case of K12 ('R-4') (Table 4). Inactivation of kanamycin has the same co-factor requirement as that of chloramphenicol (Table 4).

Table 1

Exp. 1. Co-factor requirement for chloramphenicol inactivation by the *D-C* fraction of K12 ('R-4')

System	Growth inhibition by residual chloramphenicol (%)
Complete system	7
" - Coenzyme A	90
" - Acetate ion	89
" - ATP	86

Exp. 2. Co-factor requirement for chloramphenicol inactivation by the A-50 *CM* fraction of K12 ('R-4')

System	Rate of inactivation ($\mu\text{g}/15 \text{ min}$)
No addition	0
+ Acetyl-coenzyme A	17
+ ATP, coenzyme A	0
+ ATP, coenzyme A, 100 S fraction of K12 <i>CS-2</i>	13

Exp. 1. The complete system contains 0.1 mg protein of the 'R-4' *D-C* fraction, 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M KCl, 4 μmoles ATP, 0.04 μmoles coenzyme A and 50 μg of chloramphenicol in a total volume of 0.5 ml. The mixtures were incubated at 37° C for 30 min. A 0.05 ml. portion was pipetted into 5 ml. of peptone-glucose medium prewarmed to 80° C, and heated for 5 min. After cooling, each tube was inoculated with about 10^7 cells of *E. coli* K12 *CS-2* and the growth inhibition was measured as described in the text.

Exp. 2. The reaction system contains 50 μg protein of the A-50 *CM* fraction in a solution of: 0.10 M *tris* buffer (pH 7.8), 0.06 M KCl, 0.01 M magnesium acetate and 30 μg of chloramphenicol in a total volume of 0.5 ml. The following co-factors were added: 0.2 μmoles acetyl-coenzyme A; 2 μmoles ATP and 0.02 μmoles coenzyme A; 2 μmoles ATP, 0.02 μmoles coenzyme A and 150 μg protein of the 100 S fraction from K12 *CS-2*. The mixtures were incubated at 37° C for 15 min. A 0.1 ml. aliquot was pipetted into 5 ml. of peptone-glucose medium (at 80° C) and the rate of drug inactivation was estimated as described in the text.

Table 2. CO-FACTOR REQUIREMENT FOR INACTIVATION OF DIHYDROSTREPTOMYCIN BY THE *D-C* FRACTION OF K12 ('R-4')

System	Rate of dihydrostreptomycin inactivation ($\mu\text{g}/30 \text{ min}$)
Complete	25
" + Coenzyme A	28
" - ATP, CrP, CrK	0
" - Mg^{++}	< 7.5

The complete system contains 0.5 mg protein of 'R' *D-C* fraction, 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M KCl, 2 μmoles ATP, 4 μmoles creatine phosphate, 60 μg creatine kinase and 60 μg dihydrostreptomycin in a total volume of 0.5 ml. The mixtures were incubated at 37° C for 15 and 30 min. 0.05 ml. portions were pipetted into 5 ml. of peptone-glucose medium prewarmed to 80° C and heated for 5 min. After cooling, the medium was inoculated with 10^7 cells of *E. coli* K12 *CS-2*, and the rate of drug inactivation was estimated as described in the text.

Table 3. ACTIVITIES OF DRUG INACTIVATION OF THE *D-C* FRACTIONS FROM K12 *CS-2* AND K12 ('R-4')

Drugs	K12 <i>CS-2</i>	K12 ('R-4')	Control (no <i>D-C</i> fraction)
Chloramphenicol (Original concentration * 2 $\mu\text{g}/\text{ml.}$)			
After incubation			
For 10 min	80	0	
For 30 min	75	0	84
Dihydrostreptomycin (Original concentration 1 $\mu\text{g}/\text{ml.}$)			
After incubation			
For 45 min	42	8	
For 90 min	43	0	51
(Original concentration 2 $\mu\text{g}/\text{ml.}$)			
After incubation			
For 90 min	92	0	95

The reaction mixture for chloramphenicol inactivation contains 1.2 mg protein of the *D-C* fraction of K12 ('R-4') or 1.7 mg protein of the same fraction of K12 *CS-2*, 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M KCl, 4 μmoles ATP, 3 μmoles creatine phosphate, 60 μg of creatine kinase, 0.04 μmoles coenzyme A and 50 μg of chloramphenicol in a total volume of 0.5 ml. The reaction mixture for dihydrostreptomycin inactivation contains the same ingredients except that coenzyme A is omitted and chloramphenicol is replaced by 50 μg dihydrostreptomycin. The mixtures were incubated at 37° C for the indicated time intervals and 0.05 ml. or 0.10 ml. portions were pipetted into 5 ml. of peptone-glucose medium (at 80° C). The rate of drug inactivation was estimated by the method described in the text.

* The original concentration refers to the concentration of the drug present in the peptone-glucose medium when no drug inactivation takes place.

Table 4. INACTIVATION OF KANAMYCIN BY THE ENZYME PREPARATIONS FROM *E. coli* K12 ('R-5'), K12 ('R-4') AND K12 *CS-2*

Exp. 1. Experiments with the *D-C* fractions

Source of <i>D-C</i> fraction	System	Inactivation of kanamycin ($\mu\text{g}/2 \text{ mg protein}/45 \text{ min}$)

" - ATP	1
" - Acetate ion	0
" - <i>D-C</i> fraction from <i>CS-2</i>	1
" - Mg^{++}	3
Complete system replaced with Acetyl-coenzyme A *	19

Exp. 1. The complete mixture contains 2 mg protein from the *D-C* fraction of either K12 ('R-5'), K12 ('R-4') or K12 *CS-2*, 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M KCl, 10 μmoles ATP, 4 μmoles creatine phosphate, 60 μg creatine kinase, 0.04 μmoles coenzyme A and 60 μg of kanamycin in total volume of 1.0 ml. The mixture was incubated at 37° C for 45 min. 0.10 ml. portions were pipetted into 5 ml. of peptone-glucose medium prewarmed to 80° C, and heated for 5 min. After cooling, the medium was inoculated with 10^7 cells of *E. coli* K12 *CS-2*, and the rate of kanamycin inactivation was estimated as described in the text.

Exp. 2. The complete system contains 30 μg protein of the A-50 *CM* fraction of 'R-5', 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.1 M KCl, 0.02 μmoles coenzyme A, 0.2 mg protein of the *D-C* fraction from *CS-2* and 30 μg of kanamycin in a total volume of 0.5 ml. The mixtures were incubated at 37° C for 120 min, and further procedures were carried out as described in Exp. 1.

* ATP, creatine phosphate, creatine kinase, coenzyme A and the *D-C* fraction from K12 *CS-2* were replaced with 0.7 μmoles of acetyl-coenzyme A.

The activities of the drug-inactivating enzymes were determined in the following ways:

Assay of inactivation of chloramphenicol. The total reaction mixture for the inactivation of chloramphenicol contains 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M potassium chloride, 2 μmoles ATP, 0.02 μmoles coenzyme A, an appropriate amount of chloramphenicol (20–100 μg) and the enzyme preparation in a total volume of 0.5 ml. After incubation at 37° C for various time intervals an aliquot originally containing 5 or 6 μg of chloramphenicol is pipetted into 5 ml. of peptone-glucose medium which was prewarmed at 80° C and heated for 5 min at this temperature to denature the enzyme. The medium is inoculated with 1×10^7 cells of *E. coli* strain K12 *CS-2* and shaken at 37° C for about 3 h. The bacterial growth is determined by turbidity. The amount of chloramphenicol which escaped inactivation can be estimated by comparison with suitable control tubes which contain graded amounts of chloramphenicol and heat denatured reaction mixture. The activity of the enzyme fraction is expressed by the rate of inactivation of the drug.

Assay of inactivation of dihydrostreptomycin. The composition of the reaction mixture is as follows: 0.10 M *tris* buffer (pH 7.8), 0.01 M magnesium acetate, 0.06 M potassium chloride, 2 μmoles ATP, 4 μmoles creatine phosphate, creatine kinase of 60 μg protein, 15–50 μg dihydrostreptomycin and enzyme preparation in a total volume of 0.5 ml. Other procedures are essentially the same as already described here.

Assay of inactivation of kanamycin. This was performed in a similar way to that of dihydrostreptomycin, except that 0.02 μmoles of coenzyme A was included in the reaction mixture.

Separation of Resistant Components

All operations were carried out in the cold. The 'R' 100 S fraction was treated with DNase (4 $\mu\text{g}/\text{ml.}$) and fractionated by ammonium sulphate precipitation. The precipitate formed between 30 and 65 per cent saturation was dissolved in 0.02 M *tris* buffer (pH 7.8) containing 0.05 M potassium chloride, 0.006 M 2-mercaptoethanol and 10^{-4} M ethylenediamine tetraacetate. The solution was passed through a 'Sephadex G-50' column with the same buffer to remove ammonium sulphate. This fraction was adsorbed to a DEAE-cellulose column (1 cm \times 30 cm) and eluted with the same buffer containing 0.3 M potas-

Fig. 1. Fractionation of the drug-inactivating enzymes on DEAE-Sephadex A-50. About 74 mg protein of the *D-C* fraction of K12 ('R-4') was applied to a DEAE-Sephadex A-50 column (1 cm × 25 cm) and eluted with 250 ml. of *tris* buffer (pH 7.8) containing 0.006 M 2-mercaptoethanol, 10⁻⁴ M ethylenediamine tetraacetate and a linearly increasing concentration of KCl (0.12–0.35 M). Seven ml. fractions were collected. Protein concentration was estimated by the method of Lowry ———, Protein; ○—○, *CM* inactivation, ●—●, *DHSM* inactivation

sium chloride to remove nucleic acids. The eluate was precipitated with ammonium sulphate at 65 per cent saturation, and redissolved in the same buffer (KCl 0.1 M) and dialysed over-night against this buffer ('R' *D-C* fraction).

The 'R' *D-C* fraction (about 50 mg protein) was applied to a DEAE-Sephadex A-50 column (1 cm × 25 cm) and eluted with the aforementioned buffer, containing a linearly increasing concentration of potassium chloride from 0.12 to 0.35 M in a total volume of 250 ml. Seven ml. fractions were collected and assayed for their ability to inactivate chloramphenicol, dihydrostreptomycin and/or kanamycin.

As in Fig. 1, activities for chloramphenicol and dihydrostreptomycin inactivation were eluted, showing clearly separated peaks at concentrations of about 0.22 M and 0.28 M, respectively ('A-50 *CM* fraction' and 'A-50 *DHSM* fraction'). The A-50 *DHSM* fraction inactivates dihydrostreptomycin in the presence of ATP and Mg⁺⁺. Inactivation of chloramphenicol by the A-50 *CM* fraction requires the presence of the *D-C* fraction of K12 *CS-2* in addition to ATP, coenzyme A and acetate ion. All these requirements can be replaced by acetyl-coenzyme A alone (Table 1, Exp. 2). Kanamycin inactivating activity was eluted a little behind the A-50 *DHSM* fraction (A-50 *KM* fraction), but the bulk of these two activities overlapped each other. The requirement of A-50 *KM* fraction for kanamycin inactivation is the same as that of A-50 *CM* fraction (Table 4).

Some Properties of Drug-inactivating Enzymes

Under the conditions already described, chloramphenicol, dihydrostreptomycin and kanamycin are respectively inactivated at rates of about 60 μg, 2 μg and 5 μg/min/1 mg protein of the appropriate 'R' *D-C* fraction. Heating of 'R' *D-C* fraction at 60° C for 5 min in 0.10 M *tris* buffer (pH 7.8) containing 0.01 M magnesium acetate and 0.06 M potassium chloride completely destroys dihydrostreptomycin and kanamycin inactivating activities. Chloramphenicol inactivating activity is somewhat more heat stable; more than half its activity is retained after heating at 60° C for 5 min, but it is completely abolished by heating at 80° C for 5 min.

The *D-C* fraction obtained from K12 ('R-4') grown in the presence of 4 μg/ml. of dihydrostreptomycin and 10 μg/ml. of chloramphenicol did not have higher activities of drug inactivation than that of untreated cells. Thus, inducibility of the drug-inactivating enzymes by the drugs was not observed.

Several efforts have been made to see whether tetracycline and sulphanilamides are inactivated by the extract of 'R' cells, but the results have been negative so far.

It seems that such drug-inactivating enzymes are not contained in the extract of the *in vitro* developed chloramphenicol-resistant strain or the high level dihydrostreptomycin-resistant strain selected by a single step mutation *in vitro*, since the results of experiments using cell-free amino-acid incorporating systems by us and other workers^{5,6} indicate that soluble components are not responsible for drug resistance in these cases.

The results of the work recorded here demonstrate that the extract of K12 ('R') contains separate enzymes which can inactivate chloramphenicol, dihydrostreptomycin and kanamycin, respectively; comparable activities are not observed with the extract of the sensitive strain or the *in vitro* developed chloramphenicol-resistant strain. Moreover, kanamycin inactivation is observed only in the case of K12 ('R-5'), but not in the K12 ('R-4'). It is very probable that the resistance of 'R' cells to these drugs is caused by these enzymes which are produced by 'R' genes.

The acetyl-coenzyme A requirement for chloramphenicol and kanamycin inactivation strongly suggests that the reactions may be acetylation of some group(s) in the drug molecules. The mode of dihydrostreptomycin inactivation is not so clear at present.

It was already observed by Miyamura *et al.*⁷ that the culture of the 'R' strain inactivates chloramphenicol in the growth medium more rapidly than that of the drug sensitive strain or the *in vitro* developed chloramphenicol-resistant strain does. Similar findings were recently reported by Tsukamoto *et al.*⁸ on chloramphenicol, dihydrostreptomycin and tetracycline inactivation. Our present results afford the enzymatic basis to these *in vivo* findings except for the case of tetracycline. Although at present we are unable to demonstrate inactivation of tetracycline or sulphanilamides by the extract of the 'R' strain, it is possible that, in these cases, similar inactivating enzymes may be found under appropriate conditions.

The mechanism of drug resistance of the 'R' strain seems to be of some practical interest. The drug inactivating enzymes may serve as tools in clinical and experimental researches. If the precise mode of the inactivation is elucidated, it will be helpful to obtain derivatives of the drugs which are effective against 'R' cells, as was the case of penicillinase-resistant penicillin derivatives⁹.

We thank Drs. J. Tomizawa and T. Komai for their advice. The four drug-resistant strain of *Shigella* is a kind gift of Dr. R. Nakaya of our Institute, and Drs. Sasagawa and Ikemura, of Niigata Prefectural Institute of Health, kindly supplied the five drug-resistant strain of *Shigella*.

ASTRONOMY

Stability of Rotating Massive Stars in General Relativity

THE suggestion by Hoyle and Fowler¹ that stars with masses of 10^6 – $10^{10} M_{\odot}$ may provide the energy for radio sources, and the subsequent discovery of quasars, has stimulated considerable interest in the structure of very massive stars². Iben³, using a binding-energy argument, showed that within the framework of general relativity a spherical massive star becomes unstable long before it has contracted to the stage at which nuclear reactions become important. A similar conclusion was obtained by Chandrasekhar⁴, using a detailed stability analysis on the spherically symmetric relativistic equations and calculating the relaxation oscillations from a variational principle. Similar results have been obtained by Fowler⁵ using a virial theorem approach.

In a recent publication, Roxburgh⁶, using a virial theorem approach, found that rotation had a considerable stabilizing effect, changing the radius at which instability occurred by a very large factor. In view of the large change produced by rotation it is desirable to have a proper stability analysis of rotating massive stars in general relativity, since, in the Newtonian theory, it is known that the virial theorem gives results that may be wrong by a factor of four⁷. We have recently undertaken such an investigation which will be published in detail elsewhere⁸; here we wish to report the principal results.

The general relativistic equations have been given by Misner and Sharp⁹ and by Chandrasekhar¹⁰ in a weak field approximation. This is sufficient for our purpose. If we confine our attention to slow rotation and integrate the equations over latitude, so, leaving purely radial variables, the equations that govern the structure of the rotating massive star can be expressed as¹¹:

$$\frac{2}{3}\Omega^2 r - \frac{1}{\rho} \frac{dP}{dr} - \frac{GM_r}{r^2} \left(1 + \frac{P}{\rho c^2} + \frac{2GM_r}{rc^2}\right) - \frac{4\pi GPr}{c^2} = 0 \quad (1)$$

$$\frac{dM_r}{dr} = 4\pi r^2 \rho \quad (2)$$

$$\rho = \rho_0 + \frac{3U}{c^2}, \quad \frac{U}{\rho} = \frac{3(\gamma-1) - \beta(3\gamma-4)}{\gamma-1} \quad (3)$$

$$\frac{d \log P}{d \log T} = \frac{(32 - 24\beta - 3\beta^2)}{(8 - 6\beta)} \simeq 4 - \frac{3\beta^2}{8}, \quad \beta \ll 1 \quad (4)$$

$$P = P_g + P_R = P_g/\beta \quad (5)$$

$$P_g = \frac{R}{\mu} \rho_0 T, \quad P_R = \frac{aT^4}{3}$$

Equation 4 is the adiabatic condition which is used since the star is in convective equilibrium^{1,4}.

With $\beta \ll 1$ these equations are the same as those of the polytrope $n = 3$, and the equations are readily integrated. β is then given by Eddington's¹² equation which approximates to:

$$\beta = 8.6 \left(\frac{M}{M_{\odot}}\right)^{\frac{1}{2}} \quad (6)$$

By introducing suitable dimensionless variables equations (1)–(5) reduce to:

$$\frac{d\sigma}{d\xi} = (1 + 3q\sigma) \left[\frac{1}{3}\alpha\xi - \frac{m}{\xi^2} \left(1 + \frac{q\sigma}{1 + 3q\sigma} + \frac{8mq}{\xi}\right) - q\xi\sigma^4 \right] \quad (7)$$

$$\frac{dm}{d\xi} = \xi^2 \sigma^3 (1 + 3q\sigma) \quad (8)$$

where:

$$\alpha = \frac{\Omega^2}{2\pi G\rho_c}, \quad q = \frac{P_c}{\rho_c c^2} \quad (9)$$

The former measures the degree of rotation, the second the effects of general relativity. These equations are readily solved subject to the boundary conditions:

$$\sigma = 1, m = 0(\xi^3) \text{ at } \xi = 0 \quad (10)$$

To calculate the stability against radial oscillations we introduce an adiabatic displacement $\Delta r = r e^{i\omega t}$ into the general relativistic equations and linearize in the perturbations. After some elimination, this gives an eigenvalue equation to determine ω^2 and η . It can readily be shown that the problem is self-adjoint and a variational principle derived to determine ω^2 . This gives:

$$\begin{aligned} \Sigma^2 \left[\int_0^{\xi_1} B \sigma^3 (1 + 3q\sigma) \left(1 + \frac{4mq}{\xi}\right) \eta^2 \xi^2 d\xi \right] \\ = \int_0^{\xi_1} B \sigma^3 \left\{ \left(1 + \frac{4mq}{\xi}\right) \left[\frac{\Gamma\sigma}{4} (\xi\eta' + 2\eta)^2 + \alpha(1 + 3q\sigma)\eta^2 \xi^2 \right. \right. \\ \left. \left. + 2\eta^2 \left(\sigma' \xi - (1 + 3q\sigma) \frac{m}{\xi} \right) \right] - 2q\Gamma\eta \frac{m}{\xi} \sigma (\eta' \xi + 2\eta) \right. \\ \left. - \eta^2 \frac{mq}{\xi} \left(2\sigma + 20 \frac{m}{\xi} \right) \right\} d\xi \end{aligned} \quad (11)$$

where:

$$B = \frac{e^{-4q\sigma}}{e^{-4q}}, \quad \Sigma_2 = \frac{\omega^2}{4\pi G\rho_c} \quad (12)$$

$$\Gamma = 4/3 + \beta/6$$

To calculate Σ^2 we took a trial function:

$$\eta = \xi + \lambda_1 \xi^2 + \lambda_2 \xi^3 \quad (13)$$

where λ_1 and λ_2 are parameters to be varied so as to obtain the minimum value of Σ^2 . We initially set $\lambda_2 = 0$ and varied λ_1 so as to minimize Σ^2 ; with this value of λ_1 , λ_2 was then varied to obtain an improved value of Σ^2 . The accuracy of our solution was estimated by applying the principle to the non-relativistic case, and comparing with the results of Cowling and Newing⁷. Our trial function gave considerably better results than the linear trial function.

With Γ given by equation (12) and β by equation (6) we evaluated Σ^2 for $M/M_{\odot} = 10^6, 10^7, 10^8, 10^9$ and 10^{10} for different values of q and α . Instability was found to set in when:

$$q_1 = 0.425 \left(\frac{2GM}{Rrc^2} \right) = 0.55 \left(\frac{M}{M_{\odot}} \right)^{\frac{1}{2}} + 0.56 \alpha$$

Since the massive object is like a polytrope of index 3, the maximum possible value of α is 3.95×10^{-3} (ref. 13). With $M/M_{\odot} = 10^{10}$ and α at this maximum value, the radius at which instability sets in is decreased by a factor of 400. Even small values of α can have a consider-

able effect. For sufficiently large masses and maximum α , the star becomes unstable at a radius:

$$R_I = 193 R_g$$

where R_g is the Schwarzschild radius $2GM/c^2$.

This should be compared with the results of the virial theorem analysis of Roxburgh⁶ which gave $R_I = 250 R_g$. The detailed analysis therefore confirms the general conclusions of the virial theorem analysis.

PHYSICS

Effect of Ultra-violet Irradiation on the Electrical Conductivity of Zinc Oxide Single Crystals

EXTENSIVE examination of ZnO crystals and powder in the past few years has been reported by Heiland *et al.*¹ for its optical and electronic properties. Present measurements have been initiated because of the effect of the solar ultra-violet energy on thermal control coatings of spacecraft which use ZnO as a pigment with an adequate binder. Previous measurement of electrical conductivity of ZnO, with and without doping, indicated that the increase in conductivity with doping is due to the donors as charge carriers. Optical measurements^{1,2} indicated that when the specimens have been heated in ZnO vapour the unresolved peak near the absorption edge is more pronounced, and this was attributed by Scharowsky² to be due to the absorption of zinc ion, while Heiland *et al.*¹ considered this to be due to unspecified lattice defects resulting from the diffusion of atomic zinc. Craeynest *et al.*³ explains a similar effect by reflexion spectra in powders and proposes a complex centre with an unpaired electron, but he could not detect any band at 380 nm by heating ZnO powders in nitrogen or argon atmosphere.

Single crystals of ZnO were obtained from Minnesota Mining and Manufacturing Co., which have less than 55 parts per million impurities other than zinc. A hexagonal bar was cut from the central portion of the crystal rod to give it a constant dimension. The face area and the length of the crystal was measured with a microscope which enabled us to calculate the volume of the crystal. Volume was also calculated by knowing the density and weighing the crystal on a semi-microbalance. The two methods differed by only 1 per cent. For conductivity measurements a thin coating of DuPont silver-conducting paint No. 4317 was used, and the crystal was mounted on a substrate which could withstand temperatures up to 400° C and would sustain a high vacuum. Conductivity was measured at 25° C by measuring the potential drop across a standard high resistance in series with the crystal, with the help of a Kiethly 610B electrometer. To avoid heating the crystal, a potential of 3 V was used. Cur-

rent was allowed to develop through the crystal for 10 min and the potential drop was recorded on a chart recorder.

The resistance measurement of the crystal was carried out in an atmosphere of air and dry nitrogen. Measurements were also taken when the crystal was placed under vacuum and before ultra-violet irradiation was initiated. An Ultek Corporation vacuum system was used, having sorption rough pumping and ion fine pumping so that no contamination occurred on the crystal. The vacuum was maintained at $4-7 \times 10^{-7}$ torr. The ultra-violet irradiation was performed with a BH6 high-pressure mercury arc lamp controlled by a constant intensity device developed by Arnett⁴. The irradiation was filtered using a CS7-37 Corning filter so that the principal illuminating wavelengths were concentrated about 3650 Å. The sample was irradiated for 50 h at 0.013 W/cm². When the irradiation was stopped, the sample was allowed to cool from the irradiation temperature of approximately 60° C to 25° C. The resistance was then measured while still under vacuum. Air was then allowed to enter the vacuum chamber until atmospheric pressure was attained and the resistance was again measured. The results are shown in Table 1.

Electrical conductivity in ohm ⁻¹ cm ⁻¹	Time (min) after potential is applied			
	0	4	8	10
Before irradiation	5.50 $\times 10^{-3}$			4.685 $\times 10^{-3}$
in air				
After irradiation	7.127 $\times 10^{-3}$	9.528 $\times 10^{-3}$	1.003 $\times 10^{-2}$	1.003 $\times 10^{-2}$
in vacuum				
After irradiation	4.685 $\times 10^{-3}$	4.78 $\times 10^{-3}$	4.499 $\times 10^{-3}$	4.499 $\times 10^{-3}$
and letting air				
in vacuum chamber				

The observed increase in conductivity after 50 h of ultra-violet irradiation may result from the loss of oxygen from the sample, while the excess zinc atoms become ionized and diffuse into interstitial position in the lattice, which accommodates them. The oxygen evolved will be absorbed by the ion pumps of the system and so there is little possibility of it being re-absorbed by the crystal itself. Electrons which make possible an electric conduction are removed from zinc, compared in a similar way with thermal excitation, as reported by Scharowsky². The increase in conductivity of the crystal implies that the zinc atoms are not electrically neutral. However, lowering the conductivity by allowing air to enter the vacuum chamber gives an idea of the dependency of conductivity on oxygen pressure and the influence of chemisorption of oxygen as reported by Kokes⁵. Mollow⁶ concludes, on the basis of heating crystals in hydrogen, that the change in conductivity with time is due to a diffusion process. It seems probable that the effect of heating may be comparable with the effect of ultra-violet irradiation, but no definite picture could be drawn. Further measurements of magnetic and optical properties are expected to give interesting results.

One of us (R. B. L.) is a recipient of a post-doctoral research associateship of the U.S. National Research Council-National Academy of Sciences. We thank Mr. William C. Snoddy for his advice; Mr. Max Harper for assistance in preparing the vacuum apparatus; and Mr. Charles Cooper for his help in mounting the crystal.

Tschebychev Approximation to the Equation of Thermogravimetric Data

THE use of approximate expressions rather than tabulations for non-elementary functions, such as the exponential integral, is often predicated on the simplicity of computation and the attainable accuracy. Since approximations receive quite wide usage, it is generally recognized that many expressions of varying degrees of complexity and precision are available. However, it is not so widely realized by workers not directly concerned with numerical analysis that techniques exist which may be used to obtain maximum accuracy from given functional forms by varying appropriate constants within the expressions. Procedures which best achieve the desired result require that the constants be selected such that the maximum deviation of the approximant from the exact function be minimized over the selected range of the independent variable. This is a statement of the Tschebychev criterion (for a brief introduction see ref. 1). It is the purpose of this communication to present a Tschebychev approximation to the function $p(x)$, given by Doyle² as:

$$p(x) = e^{-x} x^{-1} - \int_x^\infty e^{-\tau} \tau^{-1} d\tau = e^{-x} x^{-1} - E_1(x)$$

which occurs in the equation of the thermogravimetric data plot.

Doyle² indicates that the use of truncations of the Schlömilch expansion yields:

$$p(x) \sim f(A, x) = (x + A)^{-1} x^{-1} e^{-x}, x \geq 10$$

where A is 1 for the two-term expansion, and 2 for the three-term expansion.

The functional form, sufficiently simple for computation, possesses maximum relative errors of -7.2 per cent and +1.3 per cent, respectively, for $x \geq 10$. It is clear that some different selection of A should permit a higher accuracy with no increase in complexity.

To accomplish the fit, we seek to minimize (relative deviation):

$$\max_{x \geq 10} \left| \frac{e^{-x} x^{-1} - E_1(x) - (x + A)^{-1} x^{-1} e^{-x}}{(x + A)^{-1} x^{-1} e^{-x}} \right|$$

that is, select A such that:

$$\delta = \min_A \max_{x \geq 10} |1 - x(x + A) e^x E_1(x)|$$

The normal error curve for a problem of this type will possess two extrema, $\pm \delta$, the location of which may be obtained by application of the Remes second algorithm^{3,4}. The algorithm is effected by: (1) assuming a set of abscissae for which extrema might be expected (for example, $x_1 = 10$, $x_2 = 50$); (2) solving for A and δ (deviation of $+\delta$ at x_1 , $-\delta$ at x_2); (3) determining the abscissae of the true extrema of the resultant error curve; (4) using these as elements for a continuing iteration. This can easily be done for the foregoing function yielding:

$$x_1 = 10, x_2 \sim 27$$

$$A = 1.8768$$

$$\delta = 2.0 \times 10^{-3} = 0.2 \text{ per cent, } x \geq 10$$

It should be noted that an improvement of an order of magnitude is obtained over the relative error of the three-term Schlömilch expansion.

Table 1. $p(x)/f(A, x)$

x	Schlömilch three-term ($A = 2$)	Tschebychev fit ($A = 1.8768$)
10	1.013	1.0020
15	1.007	0.9990
20	1.003	0.9982
25	1.002	0.9980

Calculations with Two Nearly Equal Quantities

DR. WORRELL¹ has suggested that, when a small signal is to be detected against a large background, more reliable results can be gained by using ratios of observations than by using differences. For example, in a counting experiment where S events in a standard interval are to be detected against a background of B events, he shows that the relative error in $S = (S + B) - B$ is:

$$e_s = \sqrt{\frac{S + 2B}{S^2}}$$

while the relative error in $R = (S + B)/B$ is:

$$e_r = \sqrt{\frac{S + 2B}{B(S + B)}}$$

for large values of B .

For small values of S , e_r is clearly much smaller than e_s . While this result is indeed entirely reliable, its importance is not clear. If $S/B \rightarrow 0$, e_s becomes large compared to 1 for any finite value of B , while

$$e_r \rightarrow \sqrt{\frac{2}{B}}$$

which can be made as small as desired by using long counting times. Hence no indication is given that S even exists, but R can readily be found to high accuracy.

The drawback is that the value of R so accurately found is $1.0 \dots$, which physically leads to the identical result that no indication at all is given that S even exists.

The quantity of physical significance is, of course, not R but $(R - 1)$, since it is only the changes in R from unity which can carry any information as to the existence or magnitude of S .

Now:

$$R - 1 = \frac{B + S}{B} - 1 = \frac{(B + S) - B}{B}$$

The relative error in this is:

$$\sqrt{\frac{S + 2B}{S^2}}$$

or exactly e_s , again for large values of B . The gain in reliability of the value of R is thus of no practical interest.

J. H. FREMLIN

Department of Physics,
University of Birmingham.

¹ Worrell, F. T., *Nature*, **207**, 621 (1965).

WHILE most of the points in the foregoing communication are correct, I believe that Fremlin has misinterpreted my remarks. There seem to have been two points in my letter that were not clearly made. One was the nature of the experimental situation in which the ratio calculation was found to be useful: the other was my statement that "information can be extracted with greater reliability by taking the ratios rather than the differences". This state-

ment was not meant in a precise sense. Indeed, it is clear that if you calculate S from $S = B(R - 1)$, where:

$$R = \frac{S + B}{B}$$

you are bound to end up with the same error as you would have if you have calculated S from $S = (S + B) - B$. The accuracy of S does not depend on the method by which it is calculated. What was meant by the statement quoted may be clearer after the discussion which follows.

The derivation which I presented in my communication had the following basis: (1) it is well known that any experimental procedure which requires calculation of the desired result by subtracting two nearly equal quantities should be avoided if there is an alternative, because of the large errors that will result; (2) in just such an undesirable situation I found that I could get a clear indication that the phenomenon of interest existed by plotting the ratio of the two measured quantities versus time, whereas a plot of the differences versus time showed so much scatter that I hesitated to say that the phenomenon existed.

In our experiments, measurements were being made of the intensity of the 3914 Å radiation in the permanent airglow. This radiation is usually only detectable above the background of scattering from the lower atmosphere at twilight, during which period its intensity is decreasing with time. The signal intensity can be found by taking repeated measurements of signal-plus-background ($S + B$) and background (B) and subtracting corresponding pairs of readings. Under marginal seeing conditions, the experimenter may be confronted with a plot of signal versus time with such a large scatter that it is uncertain whether or not a signal is there. In such circumstances, a plot of the ratio:

$$\frac{S + B}{B}$$

versus time showed considerably less scatter than a plot of S versus time, and there was an evident peak in the ratio plot demonstrating the existence of the signal for a certain period. Thus the information that was "extracted more reliably" was that the signal was there. In my communication I chose not to discuss the question of quantitative interpretations of the ratio-versus-time plot, since that is a matter for more detailed discussions.

The symbolism which I chose in my derivation may have been misleading, since such an equation as.

$$\frac{e_S}{e_R} = \sqrt{\frac{B(S + B)}{S^2}}$$

containing S in isolation, may carry the implication that S is a measured quantity, which it is not. It may be better to state the matter as follows: If we measure two quantities, x and y , and calculate $x - y$ and x/y , then the relative errors in $x - y$ and x/y are:

$$e_{x-y} = \sqrt{\frac{x+y}{(x-y)^2}}$$

and

$$e_{x/y} = \sqrt{\frac{x+y}{xy}}$$

respectively. From these:

$$\frac{e_{x-y}}{e_{x/y}} = \sqrt{\frac{xy}{(x-y)^2}} \quad (1)$$

This ratio clearly becomes large when x and y are about the same magnitude.

In the light of this result, Fremlin's statement that e_R (or $e_{x/y}$) can be made as small as you wish by using longer counting times is seen to apply equally well to e_S

(or e_{x-y}), as I pointed out in my communication. I also pointed out that:

$$\frac{e_S}{e_R} \left(\text{or } \frac{e_{x-y}}{e_{x/y}} \right)$$

is independent of counting time, as will be evident from the foregoing equation (1). In any event, we are not at liberty to go to long counting times, as Fremlin suggests, because of the transient nature of our phenomenon.

In summary, having found a situation where the ratio of two measured quantities was undeniably more useful than their difference, I have shown that this result was predictable from error theory.

METALLURGY

Mechanism of Oxidation of Chromium Diffusion Coatings on Iron

IN recent years, we have carried out detailed investigations of the effects of time, temperature and carbon content of iron on the composition, hardness and metallographic structure of chromium diffusion coatings on iron and plain carbon steels¹⁻³. The interdiffusion process has been investigated and the values of the interdiffusion coefficients obtained. The mechanism of chromizing using a chromium-cryolite medium has been determined⁴ and the effects of high-frequency heating during chromizing have been examined⁵. This communication summarizes recent work on the mechanism of breakdown of chromized iron during oxidation in dry oxygen at temperatures in the range 700°–1,000° C.

A detailed investigation of the oxidation of chromized iron has been carried out using thermogravimetric, metallographic and electron-probe microanalyser techniques to establish the kinetics of the process, the redistribution of iron and chromium within the metal, and to provide detailed information concerning oxide film morphology. The chromized coatings studied were 17 and 25 μ thick and contained 2.08 and 4.85 mg cm⁻² of chromium respectively. Iron specimens for analysis were supplied by the British Iron and Steel Research Association and the coatings were prepared by Metal Diffusions, Ltd., Peterborough.

Overall, the kinetics of oxidation at all temperatures can be represented schematically as shown in Fig. 1. There were three clear stages of oxidation. The first stage AB was parabolic and this was followed by the second stage BC in which the rate of oxidation was much less than that required by the parabolic relationship. Finally, breakaway

Fig. 1. Schematic curve for the oxidation of chromized iron

Table 1. SPECIMEN LIFE AS A FUNCTION OF TEMPERATURE AND COATING THICKNESS

Oxidation temperature °C	Specimen life (h)	
	17 μ thick coating	25 μ thick coating
< 850	> 400	—
850	191	—
920	84	245
960	18	110
1,000	6.5	24

oxidation occurred and there was a rapid rise in the rate of oxidation *CD*. The useful life of the specimen corresponds to the total period *AC*. The variation of specimen life with temperature and coating thickness is shown in Table 1. It is clear that the specimen life decreased markedly with increasing temperature and that increasing the coating thickness increased coating life by a factor of about four.

At temperatures < 850° C the final breakaway stage was not observed. Chromium sesquioxide was the only phase detected in the oxide scales during exposures of up to 400 h duration at such temperatures, and the amount of iron in solid solution in the Cr_2O_3 was never greater than 3 per cent. This was true despite the fact that the chromium in the surface layer of the coating was depleted to 2 per cent (Fig. 2). At temperatures > 850° C, when the chromium was depleted to between 13 and 20 per cent in the surface layer of the coating, a thin layer of oxide containing 50–60 per cent iron and < 15 per cent chromium was formed between the metal and the Cr_2O_3 layer. Many of these regions of iron-rich oxide were examined in cross-section using electron probe micro-analysis; but the regions were generally less than 4 μ in thickness and accurate quantitative analyses could not be achieved. The ratio of concentrations of iron:chromium was generally greater than 5:1. It was not, therefore, possible to identify the oxide phase containing 50 per cent iron directly from micro-analysis as both a sesquioxide of iron-containing chromium and an iron-rich spinel are possible. However, samples of this iron-rich oxide were detached and subjected to X-ray analysis. It was found that all the lines obtained were characteristic of either chromic or ferric oxide which have similar lattice parameters. This suggested that the second oxide phase to form at the metal- Cr_2O_3 interface was a sesquioxide rather than a spinel. At later stages in the process of oxidation, when the chromium concentration at the metal surface became less than 13 per cent, chromium spinel oxides were present in the scale. It is of considerable interest to note that, in a number of scales, one or other of the sesquioxide phases was found to be missing close to breakaway. This observation implied that one or other of the phases had disappeared in producing spinels of intermediate composition close to breakaway. During the breakaway stage *CD* the oxide richest in chromium was found to contain as little as 19 per cent chromium in some areas of the scale.

Fig. 2. Secondary diffusion in chromized iron. A, Chromium concentration profile prior to exposure; B, chromium concentration profile after 360 h oxidation at 800° C

Fig. 3. The relationship between the reciprocals of the specimen life of chromized iron and the temperature of oxidation

In these specimens of chromized iron internal stresses in the oxide layers were largely relieved by creep and the formation of blisters at all temperatures between 700° and 1,000° C. Small amounts of localized cracking of the scale did occur in specimens exposed at temperatures \leq 850° C. This occurred near point B (Fig. 1) at the end of the parabolic period. Nevertheless, a period of significantly reduced oxidation then followed. At 850° C cracking at this stage was at a maximum.

The present work is of considerable interest in view of the controversy with respect to the mechanism of breakdown of protective scales on iron-chromium alloys and stainless steels⁶⁻¹². Some authors favour chemical theories involving sesquioxide-spinel transformations whereas other authors attribute film breakdown to mechanical causes. Our evidence suggests that although there may be some contribution from mechanical factors at the end of the parabolic stage, the formation of spinels is due to interaction between the sesquioxides Fe_2O_3 and Cr_2O_3 . Evidence for this, in addition to the direct evidence from X-ray and electron probe micro-analysis, can also be obtained from the following considerations. If we assume that the overall rate controlling process is diffusion it is possible to consider an overall diffusion coefficient, *D*, for the whole process of oxidation prior to breakaway. It is reasonable to suggest that if the oxidation mechanism does not change significantly over the range of temperature involved, the values of *D* might be inserted in the Arrhenius equation, inasmuch that the value of *D* would increase with increase in temperature. For a given chromium diffusion coating the amount of chromium involved is constant and thus, as *D* increases, the period of oxidation required to produce breakaway would decrease proportionally. Consequently it is also reasonable to replace the values of *D* in the Arrhenius equation by the reciprocal of the oxidation life. It can be seen in Fig. 3 that a good linear relationship is observed between $\log (1/\text{life})$ and the reciprocals of the oxidation temperatures (°K). This suggests that despite this oversimplification the Arrhenius relationship is meaningful, and this is additional evidence in support of an oxidation mechanism based on chemical changes and interdiffusion. If mechanical cracking of the oxide scales were severely to affect the process, then such a relationship would not be expected to hold. Indeed, such cracking of scales was found experimentally to be more noticeable at 850° C and the point corresponding to this temperature does not lie on the straight line in Fig. 3. We therefore take the view that at temperatures greater than 850° C there is conclusive evidence for a chemical breakdown of oxide scales during the oxidation of chromium diffusion coatings on iron.

We thank the British Iron and Steel Research Association for a supply of iron, and Metal Diffusions, Ltd., for preparing the chromized materials. One of us (D. M.) thanks the Ministry of Defence for a research bursary during the tenure of which the work was carried out.

Mechanism of Oxidation of Chromium Diffusion Coatings on Plain Carbon Steels

THE preparation and properties of chromium diffusion coatings on iron and some plain carbon steels have been discussed in detail in earlier publications¹⁻⁴. More recently we have discussed the mechanism of breakdown of chromium diffusion coatings on iron during oxidation at high temperatures⁵. Here it was indicated that the protective oxide films broke down by a chemical diffusion mechanism involving the transformation of iron and chromium sesquioxides to spinels and that extensive chromium depletion occurred in the coatings during oxidation. The present communication summarizes recent work on the mechanism of breakdown of chromized carbon steels during oxidation in dry oxygen at 700°–960° C.

A detailed investigation of the oxidation of chromized plain carbon steels containing 0.35 and 0.78 per cent carbon has been made using thermogravimetric, metallographic and electron-probe micro-analyser techniques to establish the overall pattern of kinetics, the redistribution of iron and chromium, and to provide information concerning oxide film morphology. The chromized coatings studied were 7 and 9 μ thick on the 0.35 and 0.78 per cent carbon steels respectively. The amounts of chromium in the coatings on these two steels were 4.15 and 4.67 mg cm⁻², respectively, to allow some comparison of these materials with chromium diffusion coatings on iron, which contained similar amounts of chromium. The steels used were supplied by the British Iron and Steel Research Association and the diffusion coatings were prepared by Metal Diffusions, Ltd., Peterborough.

Before discussing the results it is worthwhile to point out that the chromized zone on a carbon steel is very much different from that on pure iron. For a given chromium uptake the coating on a carbon steel is thinner and richer in chromium than a coating on pure iron. The surface chromium concentration in the coating may be as high as 80–90 per cent. The maximum hardness of the coatings was about 2,500 Vickers hardness number, and previous work^{1,2} using metallographic and X-ray techniques has shown that these coatings are rich in coarse lenticular carbides, probably (CrFe)₇C₃. This carbide is stable at high temperatures and may be expected to restrict the rate of secondary diffusion of chromium at all temperatures.

The kinetics of oxidation were of the form shown schematically in Fig. 1. As with chromized iron there were three stages of oxidation, but these were less clearly de-

Fig. 1. Schematic kinetic curve for the oxidation of chromized plain carbon steels

fined. The initial stages of oxidation were irregular and weight gains somewhat irreproducible. In some cases slight weight losses were observed. Carbon dioxide was evolved and some decarburization of the coatings occurred. In general, as with chromized iron, the useful specimen life *AB* in Fig. 1 decreased with increasing temperature and in this case also with increasing carbon content of the steel. This is clear from the results in Table 1, where data for chromized iron containing a similar amount of chromium are also given.

Table 1. SPECIMEN LIFE AS A FUNCTION OF TEMPERATURE AND CARBON CONTENT OF THE STEEL

Oxidation temperature °C	chromized iron	Specimen life (h)	
		chromized 0.35% C steel	chromized 0.78% C steel
900	> 400	52	40
930	245	40	20
960	110	22	11

The shortening of the useful life with increasing carbon content of the steel is the most noteworthy feature. Determination of chromium concentration profiles across the chromized coatings after extensive periods of oxidation (compare Fig. 2) indicated that relatively little secondary diffusion had occurred with these materials. The chromium content of the surface layers of the coatings was always greater than 50 per cent, even immediately prior to complete breakdown of the coatings. Secondary diffusion of chromium or excessive depletion of chromium from the diffusion coating was evidently not the cause of oxidative breakdown. Indeed, the coating thickness tended to increase slightly with increasing time of oxidation.

The explanation for breakdown of the coatings was determined by visual and microscopical examination of the coatings and oxide films. Quantitative confirmation was obtained by examination of the coatings and the general features of the specimens after oxidation with the electron-probe micro-analyser. In the early stages of oxidation, Cr₂O₃ films were formed. The surface of the chromized zone at the metal-oxide interface was found to be severely roughened. The evidence available suggests that preferential oxidation of the ferrite occurred, leaving carbon-rich material in the interface. The oxide film was 'pegged-in' at such points and was extremely adherent. As oxidation continued, failure occurred at the rims of the cylindrical specimens (Fig. 3). At this stage cavities were also formed at the core-coating interface. Since the oxide films were in compression, it is believed that tensile stresses were transmitted to the carbide-embrittled chromized zone which cracked at particular points of weakness, for example, specimen rims. The evidence available suggests that cracks in the coatings were in some places transmitted to the Cr₂O₃ film, which in turn cracked, thus allowing gas access to the base of the chromized zone. Electron probe micro-analyses confirmed that oxides

rich in iron formed first underneath the chromized zone, and shortly afterwards nodular growths appeared above this zone on the outer surface of the specimens. As oxidation proceeded, the number and size of such nodules increased. The outermost part of the smaller nodules consisted of chromium-rich spinel whereas the core of the nodule between the base and the outer zone consisted of iron-rich spinel. The spinels are believed to be formed by local interaction between the original chromium-rich oxides and iron oxides growing from the base of the crack. Near to breakaway, cracking of the chromized zone and cavitation at its base were extensive (Fig. 4) and nodules contained large amounts of pure iron oxides.

Samuel and Hoar⁶ suggested that the high initial chromium concentration in the coating together with the retarding effect of the carbide on secondary diffusion was responsible for the relatively low rate of oxidation of a 1.0 per cent carbon steel. The performance of a 0.4 per cent carbon steel was, however, relatively poor; this was attributed to the fracture of the chromized layer due to stresses arising from the $\alpha \rightleftharpoons \gamma$ phase changes in the core on thermal cycling. This explanation seemed unlikely to us since we have observed cracking in specimens exposed at 700° C, that is below the $\alpha \rightleftharpoons \gamma$ transition temperature. It was thought, however, that stresses might arise from differing thermal expansion characteristics of the chromized zone and the carbon steel core. Such an explanation would not, of course, depend on oxidation but merely on thermal treatment. We have found that specimens of both steels heated in argon and subjected to rapid cooling developed some degree of cavitation at the core-coating interface but no cracking was found to occur.

It is clear from the present work that the mechanism of breakaway oxidation in carbon steels is distinctly

Fig. 4. Cavitation on a specimen of chromized 0.78 per cent carbon steel oxidized almost to breakaway after 11-13 h at 960° C ($\times 400$)

mechanical in origin. Breakaway is associated with pitting, cracking and basal cavitation of the coatings, which is followed by localized breakdown of the Cr_2O_3 oxide films. Nodular growths first appear in regions of potentially high stress, that is, specimen rims, and finally over the entire specimen surfaces until breakdown of oxidation resistance is complete.

We thank the British Iron and Steel Research Association for a supply of carbon steels and Metal Diffusions, Ltd., Peterborough, for preparation of the diffusion coatings. One of us (D. M.) thanks the Ministry of Defence for the award of a research bursary during the tenure of which the work was carried out.

GEOLOGY

Organic Matter in Recent and Ancient Limestones and its Role in their Diagenesis

Hamilton and Greenfield, in their recent investigation of the organic matter associated with the calcareous sediments of Biscayne Bay, Florida, concluded from the anomalous uptake of free amino-acids, and from the difficulties encountered in washing the sediment free of ninhydrin-positive substances, that some other organic compound must be entrapped within the particles of the sediment¹. We are interested in the possibility that the organic substances postulated by Hamilton and Greenfield may be the same material as that which occurs in the Recent carbonate sediments of the Trucial Coast of the Persian Gulf, which is tentatively assumed to be a mucilaginous secretion of blue-green algae.

In all samples which have been examined from the shallow waters along the Trucial Coast, the carbonate sand grains are intimately associated with a transparent mucilaginous substance. This mucilage can easily be seen under a stereoscopic microscope when the carbonate is slowly dissolved with very dilute hydrochloric acid. As the carbonate grains dissolve, their ghosts remain outlined in transparent mucilage which occurs as a film over the surfaces of all grains, including skeletal debris, pellets,

grapestones and oolites. It lines internal surfaces, such as the chamber walls of small gasteropods and the tests of Foraminifera, and pervades the microcrystalline accretionary grains. Small colonies of single-celled blue-green algae are scattered in the mucilage, and minute thread-like tubes of mucilage extend from the algae into the carbonate of the sand grains. The close association between the mucilage and the algae suggests that it is largely a secretion of the algae. A similar mucilaginous substance also occurs in the Recent carbonate sediments of the Bahama Banks^{2,3}.

This mucilage appears to be a very stable material because it can be demonstrated that the mucilage, or a derivative of it, is also present in ancient limestones. Moreover, it plays an important mechanical part during aragonite diagenesis.

By nature of the prevailing on-shore wind and wave approach along the Trucial Coast, the Recent carbonate sediments have built out as a prograding coastal plain, which in places extends inland for up to 10 miles. In cores of sediment collected several miles inland, where the sediments must be several thousands of years old, the mucilage is still present and shows precisely the same distribution relative to the grains as it does in the sediments off-shore.

A similar, acid-insoluble, transparent substance can be seen in cores of partially cemented Pleistocene limestones beneath the floor of the Persian Gulf, some 100 miles off-shore from the Trucial Coast. Here it forms thin envelopes around the grains and also ramifies throughout accretionary grains. In some of the cores, at depths of 40 ft. below the present sea-bed, aragonite has been replaced by calcite by a process of solution of the one and precipitation of the other. It can be demonstrated that the acid-insoluble material acted as a persistent framework during this critical stage in the diagenetic evolution of the rocks and thus preserved the outlines of aragonitic skeletal debris and the internal detail of aragonitic accretionary grains. If, as the evidence suggests, the mucilage of the Recent sediments is a secretion of the algae, then these lowly plants must have played a hitherto unsuspected major role in the diagenesis of limestones.

Careful acid treatment of limestones of all ages, back to the Lower Palaeozoic, reveals the presence of an acid-insoluble transparent substance which often includes minute transparent tubes⁴⁻⁶. This substance can be made more obvious by staining with dyes, such as malachite green or methyl blue, when it becomes apparent that its distribution is analogous to that of the mucilage in the Recent carbonates. Most analyses of ancient limestones record a small proportion of acid-insoluble organic matter, usually classed as 'kerogen'. The possibility arises therefore that the kerogen of the ancient limestones may in fact be mainly a derivative of the ancient algal secretions.

GEOCHEMISTRY

Abundances of Rare Earth Elements in Eclogitic Rocks and Basaltic Achondrites

SOME similarities between the chemical compositions of eclogites and the basaltic achondrites have been pointed out by Lovering¹. In a recent neutron-activation investigation of uranium and thorium abundances² a remarkable

similarity was found in the distribution of these two elements in six eclogitic inclusions from basic breccia pipes at Delegate, New South Wales, and eight eucritic achondrites³.

Schmitt *et al.*⁴ have analysed one of the eclogitic inclusions from Delegate (sample No. R 117) and four eucritic achondrites (Juvinas, Nuevo Laredo, Pasamonte and Stannern) for fourteen rare earth elements, yttrium and scandium. They interpreted their results by calculating the absolute abundances in each sample relative to lanthanum, then expressed the relative abundance of each element as a fraction of the relative abundance of that element in chondrites. These 'normalized' values were then plotted as a function of trivalent ionic radius. From these diagrams Schmitt *et al.* concluded that the four eucrites had normalized abundances identical to those observed in the chondrites, though the absolute abundances were about twelve times higher. The eclogitic inclusion, R 117, on the other hand, was considered to show fractionation of these elements relative to chondrites.

An inspection of the analytical results indicates that the fractionation in the eclogitic inclusion of the rare earth elements, yttrium and scandium, relative to the chondritic pattern, is not as extreme as Schmitt *et al.* supposed. The apparent fractionation is due to the normalization against lanthanum, which is depleted in this specimen relative to most of the other rare earth elements. If the abundances are normalized to another element, say, samarium, the eclogite pattern becomes quite similar to that of the chondrites, and is virtually indistinguishable from the eucrites.

Fig. 1. Ratios of abundances of fourteen rare earth elements, scandium and yttrium in Stannern, Nuevo Laredo and Pasamonte, and R 117 relative to Juvinas, plotted as a function of trivalent ionic radius.

In order to compare the distribution of these elements in the eucrites and the eclogitic inclusion, it is probably safer to deal with absolute abundances, thus obviating the confusion which normalizing to a single element can introduce. To avoid the 'saw tooth' pattern which a plot of absolute abundances would yield, the abundances can then be normalized to the absolute abundances in one of the eucrites. In Fig. 1, values are arbitrarily normalized to the abundances in the eucrite Juvinas, and plotted as a function of trivalent ionic radius in the normal way.

Fig. 1 shows that first there is significant fractionation of the rare earth elements, yttrium and scandium, between the four eucrites. Secondly, the distribution of these elements in the eclogitic inclusion is not greatly different from that in the eucrites, and the differences between R 117 and Nuevo Laredo and Stannern are no greater than those between these two eucrites and Juvinas or Pasamonte.

It is apparent that the similarity between the Australian eclogitic pipe inclusions and the eucrites in their

major element chemistry and uranium and thorium contents can now be tentatively extended to the rare earth elements, yttrium and scandium.

CHEMISTRY

Cation Sites in Synthetic Zeolites

SYNTHETIC zeolites¹, especially those with the same structure as natural faujasite, have recently come into prominence as industrial catalysts. Pickert, Rabo, Dempsey, Schomaker and references² have convincingly demonstrated the importance of the positions of the exchangeable cations which compensate for the effective negative charge of aluminium atoms in the aluminosilicate framework. 'Linde' 13X normally has Na⁺ in all the cation positions. Very little attention has been given to the effect of dehydration of the zeolites on the position of the cations, or the position of individual ions when more than one type of cation is present.

We have examined the electron spin resonance spectrum of Mn²⁺ at a concentration of 1 equivalent per cent of exchangeable cations in 'Linde' 13X pre-exchanged with a variety of other ions. The Mn²⁺ ions can occupy different sites; their position depends on which other cations are present and the extent of dehydration. Fig. 1 shows the spectrum of Mn²⁺ in the hexagonal prisms which connect the sodalite cages of the faujasite framework. In these sites the cations are in distorted octahedral co-ordination. This spectrum occurs for hydrated 13X extensively pre-exchanged with Zn²⁺, Mg²⁺ or Li⁺. It is noteworthy that these ions are smaller than Mn²⁺ and have a high charge to radius ratio. They evidently prefer other sites to the hexagonal prisms. The spectra of Mn²⁺ in hydrated 13X pre-exchanged with other ions, (Na⁺), K⁺, Cd²⁺, La³⁺, Ca²⁺ show six peaks but no fine structure (Fig. 2). Pre-exchange with Ca²⁺, which cannot enter the hexagonal prisms or the sodalite cages, causes a little Mn²⁺ to enter the prisms, but most seems to remain in the cages while Na⁺ fills the prisms.

Fig. 1. The first derivative electron spin resonance absorption spectrum of hydrated 13X approximately 72 per cent exchanged with Zn²⁺ ions and 1 per cent Mn²⁺ ions, measured at 3,270 Mc/s

Fig. 2. The electron spin resonance spectrum of 13X treated with sodium acetate/acetic acid buffer, pH 5.5, and 1 per cent exchanged with Mn²⁺ ions, measured at 9,270 Mc/s

During dehydration of 13X exchanged with Zn²⁺ the spectrum of Fig. 1 remains unchanged, indicating that the Mn²⁺ remains in the hexagonal prisms but, in 13X pre-exchanged with Li⁺, Mn²⁺ leaves the prisms. Mg²⁺ gives an intermediate result. On the other hand, when 13X is pre-exchanged with Ca²⁺, Mn²⁺ enters the prisms only after dehydration at 200° C, while further dehydration at 400° C progressively releases the Mn²⁺ probably to the sodalite cages.

In our observations only the transitions between the $+\frac{1}{2}$ and $-\frac{1}{2}$ electron spin levels of Mn²⁺ can be resolved; the basic six line spectrum is due to coupling with the ⁵⁵Mn nucleus, spin $\frac{5}{2}$. The fine structure of Fig. 1 arises from transitions in which the nuclear spin also changes. The fine structure must disappear when the Mn²⁺ or its environment is in rapid motion. Thus Fig. 2 suggests that Mn²⁺ in hydrated 13X exchanged with large ions is at least partly co-ordinated to water. The proof that it is Mn²⁺ in hexagonal prisms which generates the spectrum of Fig. 1 comes both from theoretical examination and from the fact that the spectrum does not change with dehydration. The hexagonal prisms are the only sites not associated with water.

Quantitative Chromatographic Analysis of Organic Acids by Tritiating Methylation

IN fatty-acid analysis, thin-layer chromatography is a valuable technique for the separation of complex mixtures into specific groups and for separations of *cis* and *trans* isomers and certain positional isomers of unsaturated fatty acids, which cannot easily be achieved by gas-liquid chromatography.

Isotope derivative methods may be a valuable tool for quantitative evaluation of thin-layer chromatograms. Esterification with ¹⁴C-diazomethane¹ has been applied for this purpose, but the preparation of the reagent is rather complicated and expensive. We therefore applied a method according to which samples of organic acids are esterified with inactive diazomethane after exchange with tritiated water. This 'tritiated methylation', developed by Melander² and Verly *et al.*³ for the preparation of labelled methanol, was used before for the analysis of gibberellins by Baumgartner *et al.*⁴

An ethereal solution (0.2 ml.) of tritiated water, containing 6.67 μ c. in 1 μ l. water per ml. dry diethyl ether,

is added to the sample of organic acids which may be dissolved in small amounts of anhydrous diethyl ether, acetone or dioxan. The weight of the sample can amount to as much as 10 mg which corresponds to a threefold molar excess of acids with respect to the tritiated water, the average molecular weight of the acids being 300. For larger samples it is advisable to use greater amounts of tritiated water. After an exchange period of 15 min, which is found to be sufficient, the acids are quantitatively esterified by addition of an excess of an ethereal solution of diazomethane.

Afterwards, the sample is brought on to the thin-layer plate and the chromatogram developed. Spraying with 1 per cent 'Ultraphor' (BASF) in ethanol is applied for silica gel plates and 0.1 per cent 2,7-dichlorofluorescein in ethanol for silicagel plates impregnated with 20 per cent silver nitrate. The amount of spraying agent in the latter case must be as small as possible to avoid quenching in the tritium counting. The components are marked in ultra-violet light, the appropriate zones scraped off and subsequently extracted in a percolator with diethyl ether-hexane 7 : 3 (v/v) for 4 h. The solvent is evaporated and the samples are transferred to vials by rinsing with 10 ml. liquid scintillator, containing 4 g PPO and 0.1 g dimethyl-POPOP per litre toluene, and counted with a Tricarb liquid scintillation counter. If quenching is observed, corrections are made by using the channel ratio method⁵.

The essential point in the procedure is the quantitative extraction from the adsorbent. In all cases shown in Table 1, the amounts of the samples were chosen in such a way that recoveries greater than 95 per cent were ensured. For fatty acids, amounts of at least 1–5 mg of the different components in a mixture are sufficient for this purpose. Smaller amounts of the sample can be analysed by adding inactive methyl esters of the components to the esterified mixture before chromatography is applied, which is an advantage of this method. In this way, satisfactory results could be obtained in the microgram range as well. This was illustrated by analysis of a known mixture of stearic, oleic and linoleic acid with decreasing sample size. After tritiation and esterification of the samples, 10 mg of an equimolar inactive mixture of the esterified acids was added. For samples of 1, 0.1, 0.5 and 0.01 mg, the same composition was found with a standard deviation of the mean of ± 2 per cent. A number of applications of this method are given in Table 1.

Table 1. APPLICATIONS OF THE TRITIATING ESTERIFICATION PROCEDURE*†

No. of sample	Components	Molar equivalent composition (per cent)	
		Known	Found
1	Elaidic acid	49.2	47.2 \pm 1.1
	Oleic acid	50.8	52.8 \pm 1.1
2	9,12- <i>cis,cis</i> Octadecadienoic acid	31.4	32.2 \pm 1.0
	11,15- <i>cis,cis</i> Octadecadienoic acid	68.6	67.8 \pm 1.0
3‡	Monomeric acid	49 \pm 2	49.7 \pm 0.8
	Dimeric acid	22 \pm 1	25.8 \pm 1.7
	Trimeric acid	29 \pm 2	24.6 \pm 0.8

* Medium of tritiation is diethyl ether. Total sample weight is 10 mg. For thin-layer chromatography 'Silicagel G' (Macherey Nagel) was used for sample 3 and 'Silicagel G'-20 per cent AgNO₃ for samples 1 and 2.

† Eluents: benzene-light petroleum 7 : 3 (v/v) for sample 1, benzene-5 per cent diethyl ether for sample 2; iso octane-diethyl ether 7 : 3 (v/v) for sample 3.

‡ This sample was a commercial mixture of polymerized C₁₈-acids of known composition.

The total yield of incorporation of tritium per sample was small and variable (1–7 per cent of the total activity of the tritiated water). This is not due to an incomplete reaction, since no significant difference in the incorporated tritium activity was found when the time of the tritium exchange of stearic acid was varied from 2 to 30 min. Moreover, no apparent effect of the medium on the efficiency of tritium incorporation was found. The variations in the total incorporated activity limit the direct applicability of the method to relative figures for the composition of a given sample. When absolute information is required, a known amount of an internal standard

has to be added before tritiation is applied. The reproducibility of this method has been found to be within 5 per cent.

The analytical applicability of the method, which is demonstrated by the data of Table 1, is due to non-discriminating incorporation of tritium in the acids. On studying a number of test mixtures, it appeared that the applicability is not limited to acids with comparable dissociation constants, but that much stronger acids like dicarboxylic acids, tartaric acid, benzoic acid and phthalic acid can be directly compared with stearic acid (Table 2). On the other hand, there is an indication that phenolic compounds can also be treated in the same way. The reason for this unexpected finding may be that not only exchange of the acids with tritiated water occurs, as was supposed by Melander and Värly^{2,3}, but that also a direct acid catalysed exchange of tritium between water and diazomethane takes place, as is suggested by the experiments of Van der Merwe *et al.*⁶.

Table 2. EXAMPLES OF THE APPLICABILITY OF THE TRITIATION PROCEDURE*

No. of sample	Components	Molar equivalent composition (per cent)	
		Known	Found
1	Stearic acid	12.4	12.1
	1,12-Dodecane dicarboxylic acid	87.6	87.9
2	Stearic acid	27.0	28.3
	12-Ketostearic acid	51.0	50.8
3	12-Hydroxystearic acid	22.0	20.9
	Stearic acid	15.7	14.3
4	Benzoic acid	35.8	33.8
	Phthalic acid	48.5	51.9
	Stearic acid	21.0	21.3
	dl-Tartaric acid	79.0	78.7

* Medium of tritiation is diethyl ether or acetone. Total sample weight is 10 mg.

For thin-layer chromatography 'Silicagel G' (Macherey Nagel) was used. Eluents: iso octane-diethyl ether 6 : 4 (v/v) for samples 1, 2 and 3. Iso octane-diethyl ether 8 : 2 (v/v) for sample 4.

Special precautions had to be taken in the isolation of the more polar compounds. For quantitative extraction of *dl*-tartaric acid dimethylester, 50 mg inactive ester was added before chromatography was applied. In the case of benzoic and phthalic acid, direct counting of suspended silicagel⁷ was applied to avoid incomplete extraction. The counting efficiency, however, was low (about 3 per cent). Reliable results were obtained by adding extra silicagel to a constant weight for all components. Suspension counting cannot be applied to silicagel-AgNO₃ due to severe quenching by silver nitrate. The reliability of the tritiation procedure for a mixture of benzoic and stearic acid was also checked by tritiating known amounts of the ¹⁴C-labelled acids. After esterification, chromatographic separation and extraction, the ³H- and ¹⁴C-activities of the doubly labelled products were determined with a dual channel Tricarb liquid scintillation counter. The ³H/¹⁴C-ratios for equal molar specific ¹⁴C-activities of the two acids were the same within the experimental error of about 10 per cent.

We consider this method to be a valuable tool in the quantitative chromatographic analysis of many types of acidic organic compounds.

Mass Spectrometric Fragmentation of Nitrophenylhydrazones

In a recent communication¹ Kleipool and Heins reported the principal mass spectral features of 2,4-dinitrophenylhydrazones (DNP) of aliphatic aldehydes and ketones. Independent work in our laboratory² utilizing the identical instrument ('Atlas CH-4') confirmed their results. Particularly noteworthy are the intense molecular ion peaks, which should lend themselves to the convenient characterization of the parent carbonyl compound especially when combined with the recently described³ "in situ regeneration" technique.

Table 1. PERCENTAGE OF TOTAL IONIZATION ($\Sigma_{140}^{M^+}$) OF SELECTED FRAGMENTS OF VALERALDEHYDE NITROPHENYLHYDRAZONES

Valeraldehyde nitrophenylhydrazones	M^+	$M^+ - OH$	$M^+ - H_2O$	$M^+ - 35$	$M^+ - 42$	$M^+ - 42 + H_2O$
2,4-dinitro	19.8	—	—	0.8	7.2	19.0
<i>o</i> -nitro	6.65	1.75	12.6	35.0	3.15	2.80
<i>p</i> -nitro	32.0	—	—	—	28.16	0.96

The present report records certain experimental observations, which in part lead to a revision of the mechanistic conclusions of the Dutch workers¹ and in part shed additional light on others. Kleipool and Heins¹ noted that valeraldehyde (I) and higher aldehyde DNP derivatives display an intense peak at m/e 224 which they attribute (correctly) to β -fission of the alkyl chain with accompanying hydrogen rearrangement. Since butyraldehyde DNP does not exhibit an m/e 224 peak, they assume that a hydrogen atom in the δ -position is required which is transferred to the *p*-nitro group bearing the positive charge. In the light of the large body of information that is now available⁴ about hydrogen rearrangements this explanation seemed to us improbable. In fact, when 4,4-*d*₂-pentanol⁵ was oxidized by Barton's procedure⁶ to the aldehyde and then transformed into the deuterium-labelled DNP (II), a quantitative shift of the m/e 224 peak to m/e 225 was observed. The mechanism of this fragmentation can therefore be depicted in terms of I \rightarrow a and proceeds by the well-known⁴ rearrangement of the γ - rather than δ -hydrogen atom analogous to the McLafferty rearrangement of ketones. In contrast to the latter, hydrogen from a primary carbon cannot be abstracted in this rearrangement of DNP derivatives and thus explains the failure¹ to observe an m/e 224 peak in the spectrum of butyraldehyde DNP.

Kleipool and Heins¹ noted that the m/e 224 peak is accompanied by an even more intense one at m/e 206 which they ascribe to the further loss of water. Since aromatic nitro compounds are known⁷ to lose NO, the m/e 206 peak could also partly or totally correspond to $M^+ - 2NO$. That this process does not occur has now been demonstrated by high-resolution measurements with an A.E.I. MS-9 mass spectrometer. Kleipool and Heins¹ suggest that the aldehyde hydrogen and the *ortho* nitro group are required for this process to occur, since aldehyde *p*-nitrophenylhydrazones and ketone DNP derivatives do not exhibit this loss of water. Mechanistically, we depict this sequence in terms of b \rightarrow c \rightarrow d. This is supported further by the data for valeraldehyde DNP and its *o*- and *p*-nitrophenylhydrazones summarized in Table 1 in terms of the percentage of total ionization. It will be noted that

the sum of the $M^+ - 42$ and $M^+ - 42 + H_2O$ columns is very similar for the *p*-nitro and 2,4-dinitro derivatives, but very much lower in the *o*-nitro analogue. Evidently, this is due to a competing reaction—the extensive loss of 35 mass units, which we have shown by high-resolution mass measurements to correspond to the combined expulsion of the elements of OH and H_2O . In fact, the mass spectrum of valeraldehyde *o*-nitrophenylhydrazone also displays (see Table 1) peaks corresponding to $M^+ - OH$ and $M^+ - H_2O$. The driving force for the combined loss of OH and H_2O is

probably the great stability of the resulting ion which may be represented by e.

We thank the National Science Foundation for a predoctorate fellowship (to S. D. S.), the National Aeronautics and Space Agency for funds (grant NsG 81-60) for

the purchase of the 'Atlas CH-4' mass spectrometer, and Dr. A. M. Duffield and Dr. D. Becher for mass spectral measurements.

Electronic Absorption Spectrum of the $\text{CH}_3\text{O}\cdot$ -radical

In flash photolysis experiments involving methyl nitrite, transient absorption bands at 1999, 2036 and 2064 Å were seen¹ faintly at 50 μsec, increasing in intensity slowly to a maximum at 2.5 msec and almost disappearing by 25 msec. These bands did not appear for any other nitrite tested. The reasons¹ for these bands being attributed to $\text{CH}_3\text{O}\cdot$ (being produced originally in a metastable excited state) were that this free radical, together with $\text{NO}\cdot$, was expected to result from the alkyl nitrites which are in fact accepted sources of $\text{RO}\cdot$ (despite the early investigations² in which the primary photochemical process in CH_3ONO was deduced to be dissociation to the molecules HNO and H_2CO), the observation of the expected partner fragment NO at the smallest delay times (50 μsec), and the virtual elimination of HNO , HCO , and formaldehyde in an excited state as the appropriate carrier.

Because methoxyl is the first alkyl homologue of hydroxyl, a consideration of the known electronic structure and transitions of the latter may be pertinent to a discussion of the possible transitions for $\text{CH}_3\text{O}\cdot$, as the replacement of the hydrogen atom by the methyl group (being completely saturated, with no easily excited electrons) should act only as a small perturbation of the electronic energy-levels resulting from hyperconjugation effects. The ground state of $\cdot\text{OH}$ is $^2\Pi$ and the first transition observed in absorption is to the $^2\Sigma^+$ state near 3100 Å. The transition may be described as one in which the unpaired electron in the $2p\pi$ orbital in the ground state is promoted to the σ^* anti-bonding molecular orbital in the $^2\Sigma^+$ state, consistent with the 20 per cent decrease of the vibrational interval in the upper state. The $^4\Sigma^+$ state in which there is one electron in each of the $2p\sigma$ and two $2p\pi$ orbitals would be the most probable low-lying metastable state. By analogy then, the methoxyl radical would also have an allowed transition to a level about 4 eV above the ground state in which the C—O stretching frequency should be distinctly smaller than the value of 1,050 cm^{-1} common for this vibration in infra-red spectra of methoxyl-containing compounds. This vibration should be readily excited in the upper state, making a progression in this vibrational interval observable, because of the increase in bond-length accompanying the occupancy of the anti-bonding orbital. In fact the observed frequency difference of approximately 800 cm^{-1} is fully consistent with the predicted spectrum, but the electronic transition itself lies at 6.3 eV, far above the corresponding $\cdot\text{OH}$ state. The vibrational interval of 800 cm^{-1} is also common as a bond-stretching frequency of first-row atoms, so that the coincidence with the theoretical prediction may be entirely fortuitous.

The energy absorbed at the maximum of the 2200 Å continuum of methyl nitrite is about 130 kcal/mole, sufficient to leave less than 90 kcal/mole to the methoxyl radical as excess electronic, vibrational and kinetic energy, after the N—O single bond is broken (36 kcal/mole (ref. 3) required) and the nitric oxide molecule may well have a small amount of vibrational excitation in the ground state (5 kcal/mole). Although there might well exist a state of $\text{CH}_3\text{O}\cdot$ similar to the $^4\Sigma^+$ state of $\text{OH}\cdot$ and lying less than 90 kcal/mole or 4 eV above the ground state, there is no reason to believe that the methoxyl radical can be formed in such a state because only a single σ -bond between N and O atoms is broken in the dissociation process. Thus $\text{CH}_3\text{O}\cdot$ would be formed in either a vibrationally or an electronically excited doublet state; if conversion to the metastable state were readily possible by some obscure mechanism, then the reverse reaction would also occur, and the life-time of the metastable state would not be nearly so great as 2.5 msec.

Following the previous assignment of these bands, the deduction was drawn¹ that the radical is reasonably stable under the conditions of temperature and pressure used.

However, published kinetic investigations of methoxyl radicals have demonstrated⁴ that there is only a small activation energy required for abstraction by methoxyl radicals, and further that there is no activation energy for disproportionation between methoxyl radicals to form methanol and formaldehyde. In other words, methoxyl radicals ought to destroy one another very efficiently, at every collision (apart from a possible steric factor). Again the analogy of hydroxyl proves illuminating: in the flash photolysis of water the hydroxyl radical lasts about 200 μsec (ref. 5) in the presence of only water or inert gases; if other hydrogen-containing gases are present the life-time is drastically reduced because of abstraction reactions. In fact this abstracting property of hydroxyl radicals has often been used⁶ to prepare other radicals trapped in low-temperature solutions. Therefore, for methoxyl radicals to last 100 times as long as hydroxyl radicals under similar experimental conditions is exceedingly difficult to reconcile with available experimental evidence.

In summary, both spectroscopic arguments based on the position or the duration of the new bands and kinetic inferences fail to support the assignment of the transient spectrum near 2000 Å (ref. 1) to the methoxyl radical, or indeed to any other small radical. The time duration definitely points to the carrier being a relatively stable molecule with a singlet ground state, HNO and CS being simple instances of this type of chemical entity.

Equation of State of Liquid-vapour Equilibrium with the Same Constants for Both Phases

As is known, the general equation of state of van der Waals, published in the year 1873, as well as its numerous modifications, expresses the relation between pressure, volume and temperature of gases-vapours and liquids qualitatively well, but generally only with a rather rough approximation with the same constants for both phases, especially for the liquid phase. Nevertheless, in view of the average experiences with these equations, several of their results, relatively, could be considered as accurate or satisfactory ones. Recent comparative calculations of Shah and Thodos¹ about the most common fourteen equations of state, based on the critical data of argon and *n*-butane, clearly confirmed anew these circumstances. They have found the formula of Redlich and Kwong² as the relatively best one by stating that "... this simple equation possesses the remarkable ability to represent the gaseous and liquid regions rather accurately"; yet they give no detailed results for the liquid states. Ree³, somewhat earlier, reached a similar conclusion that "... the Berthelot equation of state⁴ gives satisfactory results of liquid and vapour volumes in the vapour-liquid equilibrium for Ar, Kr, Xe, N_2 , O_2 , CO and CH_4 , ...", that is, they examined definitely only the volume values.

It has been recognized for a long time that the best agreements can be reached for states of low up to medium densities, where the volume dependence of pressure is not so abrupt. Incomparably more delicate is the situation at greater densities and especially for the liquid state well below the critical point, where relatively slight volume variations correspond to relatively great pressure changes. Wohl⁵, himself author of a well-known

equation of state, had already characterized in the year 1914 the difficulties in this respect by writing: "A somewhat exact calculation of the vapour pressure from the volume of the liquid by any general equation of state is, of course, excluded, as far as lower pressure regions are concerned".

A numerical presentation of these difficulties is shown in Table 1, where for liquid argon some experimental and calculated data are given, the latter obtained with the Redlich-Kwong equation which, according to Shah and Thodos, is the relatively best one (see foregoing).

We see that in case A (Table 1) the v_{calc} values obtained with the p_{exp} values, relatively, are really in fairly good agreement with the experimental values, in sharp contrast to the p_{calc} values obtained with the v_{exp} values. For temperatures nearer the triple-point the p_{calc} values are negative and, for example, for 84.15° K the absolute value of p_{calc} is even higher than p_{crit} itself. The p_{calc} values have also a positive maximum toward the critical point and higher than p_{crit} . The p_{calc} values are in part better when the constants of the equation are obtained from two extreme states of the liquid (Table 1, case B), without being satisfactory ones in this case either, and similarly having a positive maximum higher than p_{crit} itself.

For this, and other two-constant equations of similar structure, this result appears to be no surprise, and is for any liquids unavoidable, because the p_{calc} values are simple differences of two different terms (= functions) of generally much higher values than those of p_{exp} itself. For instance, in the case of argon at 84.15° K the two terms are higher than p_{exp} by about four orders of magnitudes, in that of water at 293.15° K by about six orders of magnitudes. It seems to be hardly possible that two such different and relatively simple functions could follow accurately enough the courses necessary for their differences to result in the expected p_{exp} values for broader ranges of liquid states. Thus even the Redlich-Kwong formula, considered as the relatively best simple equation of state, seems to be unsuitable for the representation of the vapour pressure values of liquids. Very probably, it is on such and further grounds (see following) that any more complete and satisfactory functional representation can scarcely be found in the literature for the pressure behaviour of liquids.

These difficulties first seemed to be consequences of the only rather approximate suppositions about the short-range molecular forces, raising hopes of better results by finding more appropriate representations of these forces. Such hopes have now been really fulfilled, although in a form notably different from that expected.

As is well known, the van der Waals equation can also be expressed for the pressure in three terms—the kinetic, attractive and repulsive ones. This structure of the expression, really, could hardly be more logical, clear and simple for the first but complete representation of all possible intermolecular forces. The unification of the

terms of attraction and repulsion into a single attractive term, as, for example, in the van der Waals and Redlich-Kwong equations, seemed to be a certain suppression of the specific course of the repulsive forces and hence to be a certain over-simplification, which really proved to be one cause, although not the only cause, of the serious difficulties of such equations.

These three separated terms could be more conveniently modified in searching for their more appropriate forms to fit better the experimental data, when the equation, originally for one mole, was reduced to that for a single molecule. Simultaneously its three-dimensional parameters v and $b = v_{\text{min}}$ were replaced by the corresponding linear parameters d and d_{min} , respectively, and the expression of the 'free volume' $v - b$ by that of the 'average free intermolecular distance' $d - d_{\text{min}}$, here denoted by λ . In recent theoretical studies the use of molecular and linear parameters is not new when dealing with problems of gases, vapours and liquids.

An extensive numerical examination of this latter type of the equation resulted in numerous cases in real solutions also for broader ranges of the liquid state, even without the presence of λ in the kinetic and attractive terms. Yet all these solutions gave a kinetic constant considerably below its normal value, clearly indicating that the solution depends also on some completely unusual modification of the equation. Really, with the normal value of the gas constant, solutions are possible with the unusual position of the λ variable specifically in the numerator of the kinetic term, in which, in order to obtain more accurate results, an exponential dependence of λ on d is required. A more generally applicable form of the equation of state was thus found as:

$$p = \frac{k}{d^3} \left(\frac{\lambda}{d} \right)^{(a/d)^n} T - \frac{f_2}{d^3} + \frac{f_3}{d^4 \lambda^2} \quad (1)$$

where k is the constant of Boltzmann, while a and n determine the height and somewhat also the course of the exponential λ -dependence. With increasing value of d the equation evidently converges into that of ideal gases.

The figure, in the customary $\log p$ versus $\log v$ representation, gives the experimental curves and some calculated data of such different substances as the strongly dipolar water and the non-dipolar carbon dioxide. The constants of the equation were calculated with the data of such wide temperature intervals of the liquid states as 20°–220° C for water and –50°–0° C for carbon dioxide, respectively (in Fig. 1 marked with \times), their values being those shown in Table 2.

Fig. 1. Experimental curves (—) and some calculated data (●) of liquid H₂O and CO₂ and that of their saturated vapour, the calculated data obtained with the given equation. (×), Basic points of calculation, (○), data of saturated vapour calculated with a van der Waals-type equation by the use of the same basic points of calculation

Table 2. CONSTANTS OF THE GIVEN EQUATION FOR H_2O AND CO_2 . THE CALCULATIONS WERE MADE WITH EIGHT NUMBERS IN ORDER TO OBTAIN SUITABLE RESULTS ALSO FOR LOWER PRESSURES

Const.	H_2O	CO_2
k	$1.3805864 \times 10^{-16}$	$1.3805470 \times 10^{-16}$
f_1	$1.8866444 \times 10^{-37}$	7.744948×10^{-37}
f_2	$5.2299157 \times 10^{-39}$	7.682670×10^{-38}
σ	7.8447519×10^{-3}	6.8015995×10^{-3}
n	0.9	1.4229
d_{min}	2.5087914×10^{-8}	2.5295745×10^{-8}

The values of the constants of Table 2 were calculated by the given form of the equation which, of course, is only an approximate one on several grounds. We will always be forced to use approximate expressions for such complicated processes of short-range molecular forces, the values of the constants being dependent therefore not only on the conceptual approximation of the problem, and even on the selected points of the liquid state used for the calculation, but also on the selected form of simplification.

The position of the points on the experimental curves used for the calculation of the constants (Fig. 1) leaves no doubt that the equation gives good to excellent results for these broad ranges of liquid states. This surprising fact means that the given relatively simple three-term equation, in comparison with the two-constant—two-term and even the more complicated formulae mentioned here, seems to contain some appropriate new step as to equations of state. Also the calculated points of the saturated vapour state, obtained, of course, with the same constants, are favourable or acceptable ones; this is especially so when it is taken into account that this is only the first stage in a new direction. The greatest divergence of the calculated pressure values is about 10 per cent for water and about 20 per cent for carbon dioxide near the critical point, generally rapidly decreasing at greater vapour volumes, and finally scarcely differing from the experimental data. The same equation, evidently, can represent the corresponding volume values of liquids with a considerably increased precision.

The essentially increased applicability of the formula presented here gives the impression that the modifications incorporated could also be of theoretical significance. Improvements and applications of the solution given and the possible or probable theoretical background will be reported separately.

I thank Prof. P. H. Emmett of the Johns Hopkins University, Baltimore, Maryland, for discussions. I also thank the Petroleum Research Fund of the American Chemical Society and the Cabot Co., Boston, for financial support.

Organochlorine Pesticides in the Atmospheric Environment

POLLUTION of the environment has long been a subject of public concern and much attention has been paid recently to the new ecological factors introduced by the wide agricultural usage of pesticidal chemicals. Contamination of soil and crops has often featured in environmental studies of these pesticides, but so far little attention has been given to atmospheric pollution, although, as long ago as 1961, Harris and Lichtenstein¹ showed that the loss by volatilization of aldrin, dieldrin, heptachlor and gamma-benzene hexachloride was a major factor in their disappearance from soils treated with these compounds. Later,

in the United States, the President's Science Advisory Committee drew attention to the fact that inhalation of air contaminated with pesticides might present a hazard to man² and recommended that air should be continuously monitored for pesticide residue levels. In 1965, an Advisory Committee of the United States Food and Drug Administration referred to studies which showed the presence of up to 0.075 p.p.m. of dieldrin in total diets³ and considered the possibility that half as much again could be absorbed from "air or other exposures".

Little practical work seems to have been undertaken to determine pesticide residues in the atmospheric environment, but in the United Kingdom, Wheatley and Hardman⁴ recently reported indications of the presence of organochlorine insecticides in rain-water collected in an agricultural area at Wellesbourne in Warwickshire. Steps were therefore taken at this Laboratory to examine rain-water collected in the Metropolitan area.

Two collecting stations were set up in Central London, one being on the roof of the Laboratory of the Government Chemist in Lambeth, S.E.1, and approximately 20 m above ground-level. The other was set up, with the co-operation of the Meteorological Office, at the London Weather Centre's station on the roof of State House, High Holborn, W.C.1, some 53 m above ground-level and about 1.45 km distant from the other station, across the River Thames. At these two stations, rain was collected in all-glass apparatus, with amber-coloured receiving vessels to reduce the incidence of photochemical degradation⁵. Samples were removed monthly for examination.

The organochlorine pesticides in the water were determined by a gas-liquid chromatographic method using electron-capture detection and silicone and 'Apiezon' columns as described by de Faubert Maunier *et al.*⁶. The limits of detection by this method were 5 parts per million-million for the isomers of benzene hexachloride (BHC) and 10 parts per million-million for the other organochlorine pesticides in general use in the United Kingdom.

The results for the months of February to July 1965, expressed in parts per million-million, are given in Table 1. Because of the small amounts of rain collected and the low levels of the pesticides found, it was not possible to confirm the results obtained for the individual samples by an alternative technique. However, at the end of the 6 months, the combined residues from each station were examined by thin-layer chromatography on silica-gel plates with hexane:acetone, 99:1, as mobile phase.

The appropriate areas of the chromatograms were eluted and the separate eluates individually re-injected on to the gas-liquid chromatograph in columns. In this way, the presence of dieldrin, *pp'*-DDT and the α - and γ -isomers of BHC was confirmed for both stations. The identity of the *pp'*-DDT from both stations was further confirmed by conversion to *pp'*-DDE by treatment with ethanolic potassium hydroxide⁷. The *pp'*-DDE formed by this reaction was identified and determined by gas-liquid chromatography.

Insufficient quantities of the residues were available to confirm the presence of β -BHC, *pp'*-TDE and *pp'*-DDE

by alternative techniques or to make an infra-red study of any of the residues⁸.

Some individual rain-water samples which had been taken between September 1964 and January 1965 at a number of other places in the British Isles were also examined. The collecting sites ranged from Stornaway in the Outer Hebrides to Camborne in Cornwall, and the samples showed residues of organochlorine pesticides in amounts similar to those found in London rain-water. Samples of snow collected in different suburban areas within 25 km of London gave similar results. The size of these other samples, and the low levels found, again precluded the application of any confirmatory technique to the individual samples, but by appropriate bulking of the residues it was possible to confirm, by thin-layer chromatography, the presence, in the rain-water and in the snow, of dieldrin, *pp'*-DDT and the α - and γ -isomers of BHC.

The levels at which these pesticides have been detected are extremely low, near to the limits of sensitivity of the delicate electron-capture detection system used. Strict precautions were taken throughout to ensure that no fortuitous contamination of samples or extracts occurred within the Laboratory. Two samples taken from remote areas of Scotland during periods of heavy rainfall showed practically no residue content and these results suggest that adventitious contamination of samples in the Laboratory was negligible.

Present results suggest that the atmosphere carries, either as vapour or by occlusion on dust particles, small amounts of the organochlorine pesticides in common use in the United Kingdom and that they are 'scrubbed out' by rain and snow.

Work is now proceeding to determine the residue levels in air samples, and preliminary results show the presence of organochlorine pesticides in the range of 10–20 parts per million-million. Most of these residues appear to be associated with particulate matter. These experiments may eventually make it possible to determine the respiratory intake by man and to compare the result with his intake from certain foods of known pesticide-levels⁹.

We thank the Director-General of the Meteorological Office for permission to quote from the London Weather Centre's records of the rainfall on the roof of State House.

BIOCHEMISTRY

Separation of High-molecular Deoxyribonucleic Acid and Ribonucleic Acid

So far there has been no really satisfactory method for the quantitative separation in high-molecular form of a mixture of DNA and RNA isolated from cells. The procedure based on the different solubility of DNA and RNA in salt solutions of varying concentration^{1–3} is quantitatively unsatisfactory. Another method uses chromatographic separation on methylated albumin^{4–7},

but involves a series of steps which entail the danger of degradation in the recovery of the macromolecule. Specifically, single-stranded DNA cannot be quantitatively recovered without loss of its high-molecular character, because complete elution occurs only at strongly alkaline pH. Nygaard and Hall⁸ have recently described a micro-method for the detection of DNA/RNA hybrids based on their adsorption on membrane filters of nitrocellulose containing material.

On the basis of the selective adsorption of single-stranded DNA on nitrocellulose fibres of a certain nitration degree (the most satisfactory preparation proved to be 'Nitrocell', supplied by the Serva Laboratories, Heidelberg), we have developed a simple method for the quantitative separation, in high-molecular form, of the two components from a nucleic acid mixture. While RNA and double-stranded DNA (dissolved in $2 \times$ standard saline citrate (SSC), pH 6.7) pass through such a column (Fig. 1), single-stranded DNA is quantitatively retained. Elution occurs only with very diluted solutions at pH > 9 (Fig. 2). The fact that the sedimentation constant ($S_{20} = 23.8$) of a single-stranded DNA from bacteriophage *FD* (courtesy of Prof. H. Hoffmann-Berling, Max-Planck Institut für Medizinische Forschung, Heidelberg) remained unchanged ($S_{20} = 22.1$) proves that the molecule size is not altered during the adsorption and elution steps.

For the isolation of the nucleic acids, approximately 6×10^6 HeLa cells, cultivated in Hanks's solution with the addition of lactalbumin hydrolysate and calf serum, were washed and gently disintegrated by repeated freezing and thawing; during the last thawing, dodecylsulphate *tris*-buffered to pH 7 was added (final concentration 0.5 per cent). The resulting viscous solution was diluted and deproteinized in the usual way by treating it twice with phenol⁹. After two-fold precipitation by 67 per cent alcohol, the nucleic acids were dissolved in $0.1 \times$ SSC, dialysed against SSC, and centrifuged for 10 min at

Fig. 1. *a*, Elution diagram of high-molecular RNA from yeast; *b*, that of a double-stranded DNA isolated from thymus. Optical densities were measured with the Uvicord (LKB, Stockholm).

Fig. 2. Elution of a circular form of the single-stranded DNA from phage, dependent on the eluting agent.

Fig. 3. Elution pattern of a mixture of RNA and DNA isolated from HeLa cells before and after transformation of the double-stranded DNA into the single-stranded form by heating

Fig. 4. 443 $O.D._{260}$ of a preheated and rapidly cooled mixture of RNA and DNA isolated from HeLa cells, which had been incubated with 3H -thymidine ($0.5 \mu Ci/ml$ medium) 24 h before collecting, were applied on top of a column of nitrocellulose (1×16 cm) and eluted as indicated in the graph. The total activity amounted to 738×10^3 and 755×10^3 c.p.m., the recoveries were 724.5×10^3 and 751×10^3 c.p.m., of which the RNA fraction contained less than 2 per cent

15,000 r.p.m. to remove any impurities. The yield amounted to 268 $O.D._{260}$. $O.D._{260}/O.D._{280} = 2.03$.

The mixture of the two nucleic acids in SSC was heated to 100° for 10–15 min to render the DNA single-stranded, and cooled immediately by pouring it into $1/3$ volume of $3 \times$ SSC, frozen at -40° . To eliminate any low-molecular fragments, the solution can be filtered through 'Sephadex G 100' and evaporated to a small volume under reduced pressure before it is applied to a firmly packed column of nitrocellulose ($1 \text{ cm} \times 12 \text{ cm}$) which has been previously washed with 0.1 M tris , pH 7, and soaked with $2 \times$ SSC. The presence of orthophosphate ions is detrimental to the adsorption step. Elution of RNA is performed with $2 \times$ SSC, pH 6–7; of the single-stranded DNA with $0.03 \times$ SSC, pH 9–9.5, in some cases with 0.01 M tris pH 11.5 or 0.01 N sodium hydroxide (Fig. 3).

The results obtained with nucleic acids from different sources are summarized in Table 1.

Preliminary experiments seem to indicate that a separation of adsorbed DNA according to molecular size but

Nucleic acid	$O.D._{260}$ applied	$O.D._{260}$ eluted with $2 \times$ SSC pH 6.7	$O.D._{260}$ eluted with $0.1 \times$ SSC pH > 9

Optical Rotatory Dispersion and Secondary Structure of Ribonucleic Acid in Mammalian Ribosomes

MACROMOLECULAR single-stranded RNA from viruses and ribosomes is now generally thought to contain short double-helical regions¹ formed when the polynucleotide chain bends back on itself. The existence of such regions was largely inferred from the changes in ultra-violet absorption which occurred on heating solutions of macromolecular RNA. What, however, is the relation between the configuration of macromolecular ribosomal RNA in solution and in the original ribosome? Yeast ribosomes have been reported to have an optical density equal to the sum of the optical densities of the separated RNA and protein². Other evidence has been obtained by measuring the changes in ultra-violet absorption of ribosomes when these are heated (and from X-ray diffraction investigations³). The increases in ultra-violet absorption which were observed were the same⁴ or about two-thirds^{5,6} of those of the isolated ribosomal RNA. Measurement of increases in ultra-violet absorption on heating mixed systems of nucleic acids and proteins is not always very satisfactory on account of turbidity changes (for example, ref. 5) and independent evidence has therefore been sought by measuring the optical rotatory dispersion curves of intact ribosomes and of the RNA and protein isolated from them.

Rabbit reticulocyte ribosomes were prepared and supplied to us by Dr. R. A. Cox of the National Institute for Medical Research, Mill Hill, London. The ribosomes were washed to remove sucrose. The protein/RNA ratio by weight in these ribosomes was 1.17. The protein and RNA were separated by a modification of the method of Cox and Arnstein⁶, which entailed treating the ribosomes with 1.5 M guanidine hydrochloride and precipitating the RNA with ethanol. The guanidine hydrochloride was removed by dialysis. During dialysis a precipitate of insoluble protein separated; this was removed by centrifugation and

optical rotation studies were made on the remaining solution. The quantities of soluble protein and of RNA isolated were 24 and 63 per cent, respectively, of the amounts originally present in the whole ribosomes. The optical rotatory dispersion curves were determined on solutions containing 30 $\mu\text{g/ml}$. RNA or 260 $\mu\text{g/ml}$. protein, using a continuously recording spectropolarimeter (the Polarmatic 62, Bellingham and Stanley, London). Below wave-lengths of 230 $m\mu$ the reproducibility was low because of uncertainties in the base line, coupled with the high value of the Verdet correction factor in this range.

Fig. 1 shows the dispersion curve of the RNA component. The features of this curve are almost identical with those of rat liver RNA⁷. The optical rotatory dispersion curve of the protein component (Fig. 2) was that typical of many proteins and gave a linear Drude plot, which indicated a comparatively low helical content. When the results were plotted according to the Moffitt equation using a mean residue weight of 130, a straight line resulted and the b_0 value at pH 6.9 was 62; this suggests a helical content of only 10 per cent. On increasing the pH to 9.0, b_0 increased to 144, implying a helical content of about 23 per cent. A similar increase in helical content with increasing pH has been observed⁸ with the histone fraction 1b of calf thymus nucleohistone and is the result expected on discharging the basic amino-acid groups.

The dispersion curve of a solution of ribosomes is shown in Fig. 3. No change was observed in the shape of this curve when 10 mM EDTA was present, which implied that its features were independent of dissociation into sub-units. Fig. 3 (crosses) also shows the result of summing

Fig. 1. Optical rotatory dispersion curve of ribosomal RNA (30 $\mu\text{g/ml}$.) in 0.1 M NaCl 10 mM tris HCl pH 7.0 (—), optical density of the same solution (-----).

Fig. 2. Optical rotatory dispersion curve of 'soluble' ribosomal protein (260 $\mu\text{g/ml}$.) in 0.1 M NaCl 10 mM tris HCl pH 7.0 (—), optical density of the same solution (-----).

Fig. 3. Optical rotatory dispersion curve of rabbit reticulocyte ribosomes (71 $\mu\text{g/ml}$.) suspended in 0.1 M NaCl, 10 mM tris HCl, 1 mM MgCl_2 , (—), optical density of the same suspension of ribosomes (-----), x represents the summation, at each λ , of $(0.46 [\alpha]_{\lambda, \text{RNA}} + 0.54 [\alpha]_{\lambda, \text{protein}})$ where the $[\alpha]_{\lambda}$'s are for the separated components

the specific rotations of the protein and RNA components on the basis of 46 per cent RNA and 54 per cent protein (that is, $[\alpha]_{\lambda} = 0.46 [\alpha]_{\lambda, \text{RNA}} + 0.54 [\alpha]_{\lambda, \text{protein}}$). Within experimental error, the sum of the specific rotations of the separated components was equal to the specific rotation of the whole ribosomes. The only deviation occurred at the lowest wave-lengths when the measurements on the protein solution were least accurate.

The form of the Cotton effect and the actual rotation displayed by RNA at a given wave-length appears to be closely related to its secondary structure, and we therefore conclude that the secondary structure of RNA within mammalian ribosomes is the same as that which the RNA possesses in free solution. More precisely, if there is any internal conformation within the ribosomes which is not present in the separated RNA and protein, then this conformation does not appreciably affect the optical activity in the wave-length range corresponding to the absorption band of the bases of the RNA.

Sulphocysteine in the Urine of the Blotched Kenya Genet

THE urinary amino-acid excretion of the blotched Kenya genet was first shown to be unusual by Datta and Harris¹. In a survey of the urinary amino-acid excretion of various animals from the London Zoo, they found that the genet had an exceptionally high excretion of cystine. This was determined by paper chromatographic and polarographic analysis. A large quantity of cysteine acid was formed on oxidation of the urinary amino-acids, and it was reported that the cystine excretion was 1.0–1.5 mg

Table 1. ANALYSIS OF URINE FROM SOME GENETS

Species of <i>Genetta</i>	Vol. urine (ml./24 h)	Creatinine excretion (mg/24 h)	Total thiol after reduction (μ mol/24 h)	Total thiol after reduction of water eluate off 'Dowex 50' (μ mol/24 h)	Automatic amino-acid analysis	
					Sulphocysteine (μ mol/24 h)	1/2 cystine (μ mol/24 h)
(1) <i>genetta neumanii</i> (male)	95	101	317	279	165	46
(2) <i>genetta neumanii</i> (female)	50	92.5	230	200	100	47
	70	182	290	320	139	33
	66	70	420	270	121	48
(3) <i>tigrina</i> (male)	33	105	218	59	54	8
	62*	63*			84*	118*

Urine was reduced in an electrolytic desalter (6 min, 0.6 amp). Free thiol was then estimated by Ellman's reagent (5,5'-dithiobis-(2-nitrobenzoic acid)). Sodium cysteine sulphonate yields one molar equivalent of thiol under these conditions. The urine was passed down a column of 'Dowex 50' (10 \times 0.9 cm), which was then washed with water. The principal ninhydrin-positive materials in this fraction were sulphocysteine and taurine. Analysis was carried out using a Beckman amino-acid analyser. Sodium cysteine sulphonate 1 H₂O gave a colour yield of 61 per cent compared with leucine in this system.

* These values were obtained after allowing the animal to feed *ad libitum* on horse meat and the excretion of several other amino-acids was also increased. Other studies were made on a limited meat diet.

Urine was collected while these animals were in metabolic cages at the National Institutes of Health and was stored at 4° prior to analysis.

Table 2. EFFECT OF DIETARY VARIATIONS ON THE URINARY AMINO-ACIDS OF *Genetta neumanii* (MALE) NO. 4

Diet	Vol. urine (ml./24 h)	Creatinine excretion (mg/24 h)	Total thiol after reduction (μ mol/24 h)	Total thiol after reduction of water eluate off 'Dowex 50' (μ mol/24 h)	Automatic amino-acid analysis	
					Sulphocysteine (μ mol/24 h)	1/2 cystine (μ mol/24 h)
Control period (limited meat diet)	44	125	152	112	34	45
Oral neomycin supplement to the above diet 30 mg/day	23.5	41	204	146	97	17
	24	50	132	130	92	13
Eighty per cent cereal diet	38		255	119	78	53
Fasting for 24 h	7.6	30	18	3.5	7.4	5.3

per ml. This was unusual as it represented a greater solubility than that obtained by dissolving known cystine in a solution containing an equivalent concentration of salts and urea². In cystinuria, a human inherited metabolic disorder, cystine is excreted at this concentration but gives rise to frequent calculus formation, and there was no evidence that the genet ever formed calculi. The other interesting feature was that in human cystinuria there was a failure of tubular reabsorption of lysine, arginine and ornithine as well as cystine, whereas the genet had no disorder of basic amino-acid excretion.

In an attempt to resolve some of the anomalies, we have submitted the urine of the Kenya genet to automatic amino-acid analysis. We have found that the amount of cystine excreted by the genet was not so great as had previously been reported but was greater than that seen in a normal healthy man. However, analysis of the urine by electrolytic reduction followed by estimation of the thiol groups by Ellman's reagent, 5,5'-dithiobis-(2-nitrobenzoic acid) (ref. 3), showed that the amount of thiol liberated was greatly in excess of the amount of cystine found by automatic amino-acid analysis (Table 1).

It was then observed that there was another ninhydrin-positive substance in the urine that was eluted from the ion-exchange column ahead of taurine which had not previously been observed in urinary amino-acid analyses. It was characterized by having a ratio of light absorption at 440 m μ : 570 m μ , which was greater than that found for most aliphatic amino-acids and comparable with that of cystine. After the urine was hydrolysed (6 N hydrochloric acid for 18 h at 100° under nitrogen) this peak disappeared. It was also destroyed by electrolytic reduction. A partial purification was obtained by passing the urine through a cation-exchange resin, and eluting with water. This eluate was shown to contain only the genet substance and taurine as ninhydrin-positive material. The eluate after concentration was oxidized with bromine water followed by acid hydrolysis as before. Automatic amino-acid analysis now showed a new fast-running peak with a low ratio of light absorption at 440 m μ : 570 m μ . This was shown by high-voltage electrophoresis (Whatman 3 MM, 4,000 V, 6.8 per cent formic acid) and thin-layer chromatography (silica-gel G, Merck, solvent CHCl₃, MeOH, 17 per cent NH₃ - 2:2:1) to be cysteic acid. On the basis of these observations it was thought that the new amino-acid excreted by the genet was *S*-sulphocysteine

(cysteine-*S*-sulphonate). This substance was synthesized by the method originally described by Clarke⁴. The unknown substance was found to be identical with *S*-sulphocysteine by thin-layer chromatography and by high-voltage electrophoresis in the systems described here. Using the latter method a small quantity of the unknown substance was isolated and shown to have an infra-red spectrum identical with *S*-sulphocysteine after lyophilization with potassium bromide.

Genets belong to the family of Viverridae, but the classification of genets into individual species is confusing. Setzer⁵ describes two species of genet, *Genetta genetta* and *Genetta tigrina*, though Walker⁶ thinks that as many as six species exist. The species most readily available to us was *Genetta genetta neumanii*, which had been bred for several generations at the Washington Zoo. The urinary amino-acids from three members of this species have been investigated by us (Tables 1 and 2) and sulphocysteine was isolated from the urine of this species by the method already described. The original publication of Datta and Harris¹ referred to the high urinary excretion of cystine in *Genetta tigrina* obtained principally from the London Zoo. We have been able to study the urinary amino-acids from one of this species, which was kindly loaned to us by the Baltimore Zoo. Analysis by all the methods described above showed no significant variation from our findings with *Genetta genetta neumanii* (Table 1).

In order to investigate why the genet species in particular should have such a high sulphocysteine excretion, we measured fasting plasma amino-acid levels in one of the *genetta neumanii* by automatic amino-acid analysis, but no sulphocysteine was detected. This result indicates that the urinary sulphocysteine does not arise as a result of a renal overflow phenomenon. The urinary excretion of sulphocysteine was not significantly altered after supplementation of the genet's diet for one week with neomycin nor after altering his diet from predominantly meat to a diet containing 80 per cent cereal (Table 2). It is, therefore, thought that the sulphocysteine was not absorbed directly from the diet, nor was it the result of intestinal microbial metabolism. It was also observed that a high dietary intake of raw horse meat increased the urinary excretion of cystine and some non-sulphur containing amino-acids. Fasting the animal generally resulted in a reduction of urine output as well as in a reduction of urinary amino-acids and creatinine.

There are only a few reports of the occurrence of sulphocysteine in mammals, though it is thought to be a key intermediate in the sulphur metabolism of *Aspergillus nidulans*⁷. Sulphocysteine has been reported in small quantities in the urine of the rat⁸. Oral administration of sulphocysteine to rats caused an increase of urinary thiosulphate⁹. Of considerable interest is the isolation of *S*-sulphoglutathione from the ox lens¹⁰ and from the rat intestine¹¹. It is not known what significance *S*-sulphoglutathione has in general metabolism, but compounds of this type could be regarded as potential thiols which would not be so vulnerable to oxidation as the parent thiol itself. Biological synthesis of *S*-sulpho compounds has been shown to occur from sulphate in the rat¹¹, presumably by reduction to sulphite which then condenses with thiol groups to form *S*-sulpho compounds¹². In *Aspergillus nidulans*, the probable pathway of synthesis is by the condensation of thiosulphate with serine¹³.

These results indicate that among the genets which we have examined, the urinary cystine concentration did not exceed the solubility of cystine in urine as determined by Dent and Senior² and it is unlikely that cystine calculus formation would occur. Sulphocysteine can be estimated by polarographic analysis¹⁴ and it is possible that the values for cystine excretion by the genet as determined polarographically by Datta and Harris¹ could have appeared higher than those which we now observe by automatic amino-acid analysis because of interference from sulphocysteine and possibly other related substances present in the urine. Finally, it can be seen from Table 1 that the sum of cystine and sulphocysteine excretion is less than the total thiol detected by Ellman's reagent after electrolytic reduction. It remains possible that additional compounds of this type may be present which do not give a colour with the ninhydrin reagent.

We thank the Director of the Washington Zoo for supplying us with *Genetta genetta neumanii* and the Director of the Baltimore Zoo for loan of a *Genetta tigrina* for these investigations. We also thank Dr. Calvin E. Sevey of these Institutes for his care of the animals and Mrs. Katherine Bradley for her skilled technical assistance. This work was carried out while one of us (J. C. C.) was a visiting scientist at the National Institutes of Health, on leave from the Medical Professorial Unit, St. Bartholomew's Hospital, London.

Biogenesis of Ethylene in *Penicillium digitatum*

A NUMBER of compounds were compared to glucose as substrates for the biogenesis of ethylene in *Penicillium digitatum*. Several compounds of low molecular weight gave a greater production of ethylene by the organism than did an equimolar amount of glucose. D,L-Serine, L-serine and glycine proved to be better substrates for this purpose, with D,L-serine being the best.

NRRL strain 786 of *Penicillium digitatum* was obtained from the American Type Culture Collection and propagated on potato-dextrose-agar slants containing a small amount of water extract of orange peel. A luxuriant, sporulating mat of the fungus was grown according to the method of Wooster and Cheldelin¹ in a stationary medium. The tissue mat was removed from the medium, washed several times with glass-distilled water, and stored at -5° C under a nitrogen atmosphere. For testing substrates, the mats were thawed, homogenized in a Waring blender, and 15-ml. portions were pipetted into 50 ml. of a modified Wooster and Cheldelin medium containing 1 mmole of the substrate. Because casein hydrolysate, ammonium tartrate and asparagine were excluded from the medium the substrate served as the sole external source of carbon. The flasks were kept in a water-bath shaker for 48-72 h while the atmosphere above the media was flushed and passed through a mercuric perchlorate solution to trap the ethylene produced by the cultures. The ethylene was then released from the perchlorate solution into a suitable analysis system by adding lithium chloride to the ethylene-mercuric perchlorate complex².

Quantitative measurements of the released ethylene were made on a Perkin-Elmer model 154 vapour fractometer equipped with a two-meter activated alumina column 0.25 in. diam. The gas was initially trapped in a 5-ml. external column, packed with silica gel and immersed in a dry ice-acetone bath. The system was then purged with the helium carrier gas to remove excess nitrogen and the temperature of the external trapping column was raised to 40° C before releasing the sample into the fractometer under a pressure of 15 mm mercury. A 'thermistor'-type sensing chamber was used with a sensitivity of 1 mV.

The radioactivity of the ethylene produced from specifically labelled serine, glycine, glyoxylate and betaine was determined with a Nuclear-Chicago model 6000 'Dynacon' electrometer fitted with a 100-ml. ion chamber. The radioactivity of the ethylene produced from D,L-serine-3-¹⁴C, to which various amounts of aminopterin had been added, was determined with a Packard 'Tri-Carb' liquid scintillation counter, model 314 EX. No effort was made to determine the influence of mercuric perchlorate on the phosphorescence of the scintillating liquid, if any, as the object of this experiment was to determine the relative effects of various concentrations of aminopterin on the production of ethylene from D,L-serine-3-¹⁴C by *Penicillium digitatum*.

It can be seen from Table 1 that D,L-serine is a better substrate than glucose for the biogenesis of ethylene in *Penicillium digitatum*. These data are statistically significant at the 0.01 level.

Serine and glycine both occur in the choline cycle of the nitrogen pool. It was therefore desirable to use some specifically labelled compounds from this cycle as substrates for *Penicillium digitatum*. That radioactively labelled ethylene was produced from glyoxylate-1-¹⁴C, glycine-2-¹⁴C, D,L-serine-3-¹⁴C and betaine-methyl-¹⁴C, during a 48-h incubation period indicated that all three carbon atoms of serine can become a component of the ethylene molecule (Table 2). However, the conversion efficiency for the C-2 of glycine and C-1 of glyoxylate is quite low. Indeed, the unexpectedly high conversion efficiency of C-3 of serine indicates that both carbon atoms of ethylene are derived from C-3 of serine, and this would appear to be possible only through one-carbon metabolism.

Table 1. ETHYLENE PRODUCED BY *Penicillium digitatum*, USING D-GLUCOSE AND D,L-SERINE AS SUBSTRATES OVER A 60-H PERIOD OF INCUBATION

Culture No.	Substrate	Ethylene collected (μl.)	*Average
(1)	D-Glucose	9

			93

* Significant at 0.01 level.

Table 2. RADIOACTIVITY OF ETHYLENE PRODUCED BY *Penicillium digitatum* FROM 1 MMOLE OF SPECIFICALLY LABELLED SUBSTRATES DURING 48-H INCUBATION

Substrate	Substrate activity (mc./mmole)	¹⁴ C-Ethylene (c.p.m.)	Ethylene yield (μl.)	Ethylene activity (mc./mmole)	Conversion efficiency*
Glyoxylate-1- ¹⁴ C	7.35 × 10 ⁻²	2,710	2.5	0.011	0.151
Betaine-methyl- ¹⁴ C	1.0 × 10 ⁻¹	3,478	5.8	0.006	0.060
Glycine-2- ¹⁴ C	1.0 × 10 ⁻¹	12,537	10.9	0.012	0.116
D,L-Serine-3- ¹⁴ C	1.0 × 10 ⁻¹	23,600	1.2	0.197	1.965

* Ratio of specific activity of ethylene to specific activity of substrate.

Table 3. EFFECT OF AMINOPTERIN ON ETHYLENE PRODUCTION BY *Penicillium digitatum* FROM 1.0 MMOLE D,L-SERINE-3-¹⁴C HAVING A SPECIFIC ACTIVITY OF 4.95 × 10⁻³ MC./MMOLE

Concentration of aminopterine (mM)	¹⁴ C-Ethylene yield (c.p.m.) Experiment 1*	Experiment 2†
40	792	809
20	949	689
10	1,050	805
2	462	794
1	835	576
0	904	601

* Incubation period, 70 h

† Incubation period, 86 h

In support of the reported unusually small volume of ethylene obtained from D,L-serine-3-¹⁴C, the following considerations are offered: the 23,600 c.p.m. in the product ethylene is only 1.06 × 10⁻⁴ of the activity of the substrate serine. If 1 mole of serine is required to produce 1 mole of ethylene, then only 1.06 × 10⁻⁴ mmole of ethylene was produced. The temperature of the fractionating column in the gas fractometer was 40° C and the pressure under which the gas was introduced into the fractometer was 15 mm mercury. However, as there was a pressure drop between the gas inlet and the sensing chamber, a pressure of 10 mm is assumed.

$$V = \frac{nRT}{P} =$$

$$\frac{(1.06 \times 10^{-7} \text{ moles}) (0.0821 \text{ l. atm. deg.}^{-1} \text{ mole}^{-1}) (313 \text{ deg.})}{770/760 \text{ atmospheres}} = 26.8 \times 10^{-7} \text{ l.} = 2.68 \mu\text{l.}$$

Here the specific activity of the ¹⁴C-ethylene would be 8.9 × 10⁻² mc./mmole and the conversion efficiency would be 0.89. Likewise, if we were to assume that both carbon atoms of the ethylene molecule were derived from C-3 of serine, similar calculations would show the yield of ethylene to be 1.34 μl., which would have a specific activity of 0.178 mc./mmole. The conversion efficiency, in this case, would be 1.78 and these values are very close to those reported in Table 2.

Since all the labelled carbon atoms of the compounds used in the foregoing experiments enter transmethylation reactions, it was thought that perhaps the biogenesis of ethylene was related to transmethylation. Attempts were made to corroborate this hypothesis by conducting experiments with aminopterine, which is a specific inhibitor of tetrahydrofolic acid³. Table 3 shows that there was no correlation between the aminopterine concentration and the ethylene produced when D,L-serine-3-¹⁴C was used as the substrate. This would indicate that the tetrahydrofolic acid system does not take part, in the biogenesis of ethylene in this organism.

Concerning the metabolic route to ethylene, the present data support those of Wang and Persyn⁴, who found that the C-1 and C-6 of glucose were equally efficient in leading to the formation of ethylene in *Penicillium digitatum*. This indicates that glucose must be converted to triose phosphates before it is converted to ethylene. It is at this stage of glycolysis that the C-1 and C-6 of glucose are equilibrated through the action of triose phosphate isomerase. Burg and Thimann⁵ at first found ¹⁴C-glucose to be the only compound to yield labelled ethylene, but Burg and Burg^{6,7} have since found that C-2 and C-3 of trioses are incorporated into ethylene in apple tissue. However, Burg and Burg's results⁷ show that C-2 and C-3 of pyruvate, which are equivalent to C-2 and C-3 of serine, are equally effective in forming ethylene in apple tissue. The present work is in agreement with Gibson⁸, who found that C-3 of pyruvate is converted to

ethylene in *Penicillium digitatum* with a much greater efficiency than that of C-2 or C-1. It also supports the earlier contention of Burg and Burg⁶, and of Wang⁴, that triose phosphates are involved in the pathway from glucose to ethylene.

Characterization of Glucose-6-phosphate Dehydrogenase among Chinese

VARIATIONS in the physico-chemical characteristics of glucose-6-phosphate dehydrogenase (G-6-PD) have been described both in individuals with normal¹⁻⁴ and deficient⁵⁻¹¹ enzyme activity. Recently, Kirkman, McCurdy and Naiman¹² have reported on the characteristics in three unrelated Chinese males with G-6-PD deficiency. They found that the G-6-PD migrated slightly faster than normal G-6-PD but the migration was not quite as fast as that of (A-) G-6-PD observed in Negroes. The enzyme had slightly more thermolability, a bimodal pH optimum curve similar to that of the Mediterranean variant, abnormally low *K*_ms for G-6-P and TPN and relatively greater utilization of G-6-P analogues.

This communication reports on the character of G-6-PD in a group of normal and deficient Chinese subjects. For these investigations, blood was collected in ACD (formula A, U.S.P.) solution. G-6-PD activity was determined by the method of Glock and McHean as modified by Zinkham¹³. Purification of erythrocyte G-6-PD was performed according to the method of Kirkman *et al.*⁸. Starch-gel electrophoresis was performed as described by Shows *et al.*¹⁰.

Starch-gel electrophoresis was performed on haemolysate of 38 normal males and 29 normal females of Chinese origin. Of this group, 36 were Cantonese, 21 were Fukianese, and one each came from Shanghai, Chieking, Shangtung, Hupei and Hunan. The remaining five subjects came from the Chinese mainland, but their place of origin is unknown. All 67 were found to show the single band normally seen in Caucasians.

Detailed investigations were carried out in four normal and four G-6-PD-deficient Chinese subjects from Hong Kong. Patient 1 is a healthy 2-year-old male who has a haemoglobin level of 14-15 g per cent. The deficiency of G-6-PD was detected only following a haemolytic episode after the use of drugs. Patients 2, 3 and 4 have the typical clinical picture of congenital non-spherocytic haemolytic disease, with persistent reticulocytosis and a haemoglobin level of 6-8 g per cent.

Erythrocyte G-6-PD (expressed as units/100 ml. red blood cell) was decreased in all four deficient subjects, ranging from 0 to 15 units as compared with an average value of 228 units in Chinese controls and 210 units in Caucasian controls. Leucocyte G-6-PD (expressed as μM TPN reduced/h/10⁶ white blood cell) was also decreased. In patients 1 and 2 the values were 0.35 and 0.61 as compared with 1.05 in Chinese controls and 1.02 in Caucasian

controls. Starch-gel electrophoresis performed on purified enzyme showed patients 1, 2 and 3 having a single band which migrated 100 per cent (corresponding to that normally seen in Caucasians), while patient 4 showed a single band at 106 per cent (corresponding to that usually seen in Pamaquin-sensitive Negro males (Fig. 1)). In all four patients the K_m for G-6-P was reduced to half the normal values seen in both Chinese and Caucasian controls, but the K_m for TPN was only slightly reduced in patient 4 and not reduced in the other three. Investigations of pH optima were carried out twice on purified enzyme from each patient. Patients 1, 2 and 3 showed a single peak at pH 8, while patient 4 showed a bimodal distribution (Fig. 2). Relative thermostability studies were carried out at 41° C and there was no significant difference between the patients and controls. Finally, substrate specificity was tested with G-6-P analogues. There was a slight but definite increase of activity using both galactose-6-phosphate and 2-desoxy-glucose-6-phosphate as substrates. The increase was more marked in patient 4.

These results indicate that several variants of G-6-PD exist among Chinese. One variant (patient 4) shows a persistent non-spherocytic haemolytic anaemia associated with G-6-PD deficiency. This variant is characterized by a fast band on electrophoresis, a decrease of K_m for both G-6-P and TPN, and a bimodal pH optimum curve. This corresponds closely to the patients described by Kirkman, McCurdy and Naiman¹². Another variant (patients 2

and 3) shows a non-spherocytic haemolytic anaemia with a normal electrophoretic pattern and a single pH optimum peak at pH 8.0. A third variant (patient 1) shows a G-6-PD deficiency without spontaneous haemolytic anaemia, where the haemolytic process can be induced by toxic drug ingestion. Other variants are likely to be found as individuals with normal and deficient enzyme activity are studied more extensively from various parts of China and South-East Asia.

This work was supported by grants from the Chicago Community Trust, the Kettering Foundation and the U.S. Public Health Service (T1-HD-00036 and T1-AM-05186).

Separation Method for Melatonin in Pineal Extracts

MELATONIN, isolated by Lerner *et al.* in 1958¹ from bovine pineal glands, is the most potent agent known that makes the amphibian melanocytes lighter in colour². The physiological role of this compound in mammals^{3,4}, as well as its presence in the epiphysis of lower vertebrates⁵, has been the subject of many recent investigations. It is hard to prove the presence of melatonin in pineal tissues of various origin because it is usually present in these glands only in extremely small quantities. Investigations of the biosynthesis of melatonin offered new possibilities to demonstrate this compound in an indirect way. The presence of the synthesizing enzyme, 5-hydroxyindole-O-methyl transferase, in homogenates of pineal glands of the rat⁶ and the hen⁷ would indirectly indicate the presence of melatonin in the epiphyses of these species. Another indirect method for demonstrating melatonin in Amphibia has been described by Charlton⁸, who demonstrated an accumulation of labelled precursors of this compound in the epiphysis of *Xenopus laevis*.

Other, more direct, methods for the demonstration of melatonin have been described. The original method of Lerner *et al.*¹ requires large quantities of starting material and, for this reason, is scarcely suitable for most purposes. Prop and Ariens Kappers⁹, applying a paper-chromatographic separation method, were able to demonstrate melatonin in the pineal gland of a single rat. This procedure, however, brought about considerable pigment concentration in fractions which did not contain melatonin. The authors ascribed this phenomenon to traces of organic solvents. Quay⁹ developed a separation procedure for a number of indolic compounds, including melatonin. His

assay method, based on the measurement of the ultra-violet fluorescence spectrum, depends strongly on the presence of quenching substances. Since these are known to be present in pineal tissue¹⁰, the applicability of this method to the detection of melatonin in pineal organs is doubtful. Moreover, measurement of the fluorescence is not so sensitive as the blanching reaction of larvae of *Xenopus laevis*^{11,12}.

This report deals with a method of separating melatonin from extracts of pineal tissue. The separation is carried out by filtering the aqueous extract over 'Sephadex G 25', followed by elution with distilled water. The aforementioned blanching reaction of larvae of *Xenopus*^{11,12} was used as a bioassay for the various fractions of the eluate. Since no organic solvents were used in the procedure, 'background lightening' is absent in fractions that do not contain melatonin. The required quantity of starting material is dependent on the amount of melatonin in the gland, but it is fairly small; the recovery of added melatonin is complete. A comparative separation procedure for a number of other indolic compounds from urine has been described by Schlossberger *et al.*¹³.

The upper half of Fig. 1 is an elution diagram of a synthetic mixture consisting of the macromolecule 'blue dextran' with a molecular weight of about 2,000,000, sodium chloride as a representative of a small molecule, and melatonin. The distribution coefficients of the blue dextran and sodium chloride are 0 and 1 respectively, and the apparent K_A of melatonin is about 2.8. This is due to the adsorption of the indole nucleus of melatonin. Other concentrating agents¹⁴, which may occur in pineal tissue^{15,16}, do not interfere. The amine-containing substances serotonin, noradrenaline and adrenaline are retarded even more on the 'Sephadex'. This is due to the small carbonyl content of 'Sephadex' which, if distilled water is used as the elution medium, shows a weak ion exchange capacity.

The lower half of Fig. 1 shows the result of the *Xenopus* larvae blanching test on 'Sephadex' fractions of pineal extracts of various origin. The amount of pineal and control tissue (from other parts of the brain), used in the experiments, was 20–50 mg dry weight: this represented the pineal organs of (approximately) one cow, four lambs, ninety rats, or fifty hens, respectively. In the experiment with hen pineal glands, the bioassay remained positive after a ten-fold dilution of the fractions. This indicates that melatonin could be demonstrated in the pineal organs from only 5 hens. The amount of melatonin in the brain, however, is not constant but varies with the environmental conditions of the animal. This report only deals with the separation procedure, and not with details on the exact localization of melatonin or the factors that influence the quantities found in the brain of various vertebrates in different circumstances. Investigations are being carried

out of the localization of melatonin in various ependymal parts of the roof of the brain (for example, pineal and subcommissural organs) and of the part played by melatonin in the lightening of larvae of *Xenopus* after adaptation to complete darkness.

I thank Prof. J. C. van de Kamer for his advice, and Miss A. W. van Wijngaarden and Mr. C. W. A. C. M. Broekman for assistance.

Distribution of Collagenase in Rat Tissues

THE demonstration, recently reported from this laboratory¹⁻³, of a collagenolytic system in rat bone-cell homogenates raised several questions regarding its importance in the physiology and pathology of connective tissues. Since the activity was largely confined to a subcellular particulate fraction exhibiting a number of the features of lysosomes^{2,3}, it became important to know whether collagenase should be included in the growing list of hydrolases which seem to be characteristically contained in these bodies. By the same token it could be asked whether particle-bound collagenase was to be found equally in all tissues in which collagen turnover occurs or whether it was confined to bone-cells and thus had to be regarded as a part of a remodelling mechanism unique to bone.

Two tissues immediately suggested themselves for examination in seeking answers to these questions: liver, because of the abundant lysosomes which it contains⁴; and polymorphonuclear leucocytes the granules of which have been shown to contain many acid-hydrolases and the efficiency of which as phagocytes in inflammatory processes suggested that a collagenase might be included in their roster of catheptic enzymes^{5,7}. Preparations of these cells were accordingly assayed for collagenolytic activity along with preparations from kidney and brain which were taken as typical examples of parenchymatous organs. These were then compared with bone from the same animals.

Liver, kidney, brain and bone were collected from male Sprague-Dawley rats approximately 55 days old and immediately chilled in ice-cold Krebs-Ringer bicarbonate buffered medium, pH 7.4. Soft tissues were macerated in a mortar at 4° C and homogenized for 3 min in 0.25 M sucrose containing 1.0×10^{-3} M $MgCl_2$ using a glass homogenizer with motor-driven 'Teflon' pestle. Suspensions of bone cells, isolated as previously described¹⁻³, and suspensions of guinea-pig

Fig. 1. The upper part shows the effluent volume of synthetic melatonin eluted from a 'Sephadex' column. The lower part of the diagram shows the blanching reaction of black-background-adapted larvae of *Xenopus* after 20 min swimming in the eluates of extracts separated on the same column. ■, Larvae remain dark, □, larvae become lightened

polymorphonuclear leucocytes prepared as described by Oren *et al.*⁸ were similarly treated. Cell fractions from these tissues were isolated by centrifugation as in previous experiments^{2,3}. The 'large granule' fraction sedimenting between 700 and 15,000*g* was of special interest since it had been shown to contain most of the collagenolytic activity of bone cells^{2,3}. In addition a 'nuclear and debris' fraction (0–700*g*), a 'small granule' fraction (15,000–105,000*g*) and a 'supernate' fraction were prepared.

Substrate for the assay was rat bone collagen previously labelled *in vitro* with proline-¹⁴C using recently developed methods which yield material of satisfactory purity and high resistance to degradation by trypsin^{2,3}. Cell fractions were suspended in Krebs–Ringer bicarbonate medium pH 7.3 and promptly incubated with collagen substrate for 40 min at 37° C. Saponin, 1.5 per cent, was present to solubilize all particle-bound activity. The reaction was stopped by diluting the incubation flask contents with 3 volumes of ice-cold medium, after which the entire flask contents were ultrafiltered through 'Cellophane' under vacuum at 4° C. When ultrafiltration was complete (16 h was ordinarily sufficient) the filtrate was evaporated to dryness, taken up in concentrated formic acid, and counted in a liquid scintillation system^{1–3}. The net collagen radioactivity rendered ultrafilterable in 40 min under these conditions has been shown to reflect collagenolysis.

The significant results derived from these experiments are shown in Fig. 1 in which the relative collagenase activity in the large granule fractions derived from the various tissues is compared. It is clear from these data that collagenolytic activity was far larger in bone than any other tissue studied. Indeed, reproducibly measurable activity was found in only one other tissue, namely kidney; even that was at the borderline of the sensitivity of the method. Although other fractions from bone have been shown to contain smaller amounts of collagenase activity^{2,3}, none was found in such fractions derived from the soft tissue cells and leucocytes.

Two important conclusions can be drawn from these observations. First, it seems clear that significant collagenase-like activity is not to be found in solution or in subcellular particles of the lysosome type in several tissues which are known to contain such bodies. Particularly interesting, in view of the large variety of highly active acid-hydrolases found in them, was its absence from leucocyte granules⁶ prepared as noted here, or as in other experiments by Cagan and Karnovsky⁹. High acid phosphatase activity was found in aliquots of the same leucocyte granule preparations, thus ruling out non-specific inactivation as a cause of this finding.

Secondly, significant collagenase activity was to be found only in the large-granule fraction of bone, a tissue which not only contains large amounts of collagen but is, in addition, constantly being remodelled at a measurable rate as part of its normal physiology. Thus it would seem that significant lysosomal collagenase activity must be regarded, at least at present, as being a specific characteristic of the remodelling system of bone. Whether it is unique to bone cannot be determined from data at present available, but several lines of evidence suggest that it is probably a characteristic of remodelling connective tissues in general. While Gross has been unable to extract preformed collagenase activity from skin¹⁰, and attempts in this laboratory to find a collagenase-containing subcellular particle in this tissue have also been unsuccessful so far (unpublished observations), these failures seem as likely to reflect defects in methodology as absence of the enzyme³. Moreover, collagenolytic activity seems to increase in both skin and bone in situations where remodelling is increased—in skin in healing wounds^{10,11}, and in bone following injection of parathyroid extract⁴, or in the increased bone destruction and osteoporosis induced by heparin¹².

This work was supported by U.S. Public Health Service grant AM 00854-9.

We thank Dr. R. H. Cagan and Dr. M. L. Karnovsky for the supplies of guinea-pig leucocytes and leucocyte granules prepared by their methods used in these experiments, and Miss L. Bunde for assistance.

Fig. 1

Cystine Content of Cattle Hair

ORGANIC mercurials react with thiols or with disulphides (following their conversion to thiols by reagents such as sulphite), according to the following equations^{1–3}:

A convenient way of following the reaction in hair is to expose a known amount (10–15 mg) to an approximately four-fold excess of ²⁰³Hg-labelled mercurial such as phenyl-mercuric acetate (25 μmoles, 0.5 μc., in 5 ml.) in a 20 per cent (v/v) dimethyl-formamide solution at pH 9 containing ammonium nitrate (0.400 M), ammonium hydroxide (0.100 M), sodium sulphate (0.625 M) and sodium nitrate (1.250 M) (ref. 4). The mercurial bound to the insoluble keratin is calculated from the amount of radioactivity lost from solution after 24 h at 37° C.

One hair sample was taken from the last intercostal space on the mid-side of each of 19 and 54 animals in March and October 1961 respectively. The numbers of two-year-old Brahman, British, Brahman × British and

Africander × British crossbred steers and heifers sampled are shown in Table 1. Animals were weighed, clipped and coat scored⁵ by Messrs. H. G. Turner and A. V. Schleger. All hair was first washed with several lots of petrol ether, ethanol, and finally water, before overnight drying at 37° C. Assays were carried out on duplicate sub-samples of each hair sample, while a third sub-sample was used for dry-weight determinations. As the weighted mean mercurial binding was higher in March than in October ($P < 0.05$), the two sets of results are treated separately. The March clippings were also associated with sleeker (lower score⁵) coats. On the other hand, the difference between male and female means was not significant. This finding is in disagreement with a previous claim⁶ that female cattle hair had a higher cystine content.

The mean value for mercurial binding in each breed for March and October is given in Table 1. It is at once apparent that the mercurial binding by Brahman hair is lower than that of other breeds. An analysis of variance (Table 2) reveals that the differences between breeds are highly significant. If the Brahman hair is not taken into account, this breed difference is much reduced and indeed loses significance in March samples. The differences between samples are validated by being far greater than those between duplicates.

The breed mean mercurial binding values rank in the same order as the tolerance of a tropical environment. On the other hand, mercurial binding between individual animals within breeds and months was not significantly correlated with either the coat score ($r = -0.078$, d.f. 60), or with the October body weight ($r = +0.214$, d.f. 58).

The specificity of the reaction between mercurials and thiols^{2,3} is such that mercurial binding may be taken as an index of the cystine content of the hair samples⁴. Indeed, the range of cystine contents estimated from mercurial binding values gives figures for British cattle (Hereford × Shorthorn) of between 10.8 and 12.6 per cent. These values are reasonably close to those reported by earlier workers (11.0–14.6 per cent) (refs. 6 and 7). Exact comparison is unfortunately impossible, not only because of different environmental, nutritional and other factors, but also because different breeds are involved.

In samples selected to give the widest possible range of values, the correlation between total sulphur and mercurial binding is high ($r = +0.810$, d.f. 30, $P < 0.001$). Mercurial binding accounts for an average of 78.6 per cent ($S.E.$, 1.3) of the total sulphur (analysis by the C.S.I.R.O.

Microanalytical Service). By analogy with hair from other sources⁸, the methionine content of cattle hair is almost certainly insufficient to account for the 'missing' sulphur. Schöberl and Bisping⁷ showed that there is some cystine destruction in hair and wool as a result of solar, ultra-violet irradiation under the warm humid conditions prevailing close to the skin surface. The location of our animals at 'Belmont' near Rockhampton, just within the tropical zone, and the hair sampling in the exposed intercostal region, would both tend to favour the formation of cystine degradation products. A further possibility is that all the disulphide bonds may not be accessible to the reagent under our conditions. The fact that the reaction had apparently come to a standstill is of course no guarantee of complete accessibility.

The results on Brahman hair are compatible with a greater medullary content. It is known that medullary protein is deficient in sulphur⁹ and that Brahman type hair contains a higher proportion of medullated fibres than other breeds of cattle¹⁰. Unfortunately information on the percentage of medullary protein in cattle hair is lacking. The question as to whether the lower sulphur content and the lower mercurial binding capacity of Brahman hair is of metabolic significance is being investigated.

We thank Mr. H. G. Turner for advice and Mr. G. J. Buch and Miss C. I. Seer for assistance.

PHYSIOLOGY

Energy Requirements for Relaxation from Tonic Contractions ('Catch') in an Invertebrate Muscle

THE anterior byssus retractor muscle (ABRM) of the edible mussel, *Mytilus edulis*, responds to pulses of alternating current with a rapid phasic contraction. Stimulation with direct current or acetyl choline produces a prolonged tonic contraction or 'catch'¹, and a rapid relaxation from this catch follows the addition of 5-hydroxytryptamine (serotonin)².

Investigations of the physical properties of paramyosin isolated from molluscan muscles have led to the idea that tension is maintained during a catch through a rigid network of paramyosin crystals³. An opposing view suggested by Lowy, Millman and Hanson is that the holding capacity of the muscle depends on a sliding filament system with long-lasting cross-links⁴.

In the latter case, bonds between myosin and actin would have to be broken when the catch is released with serotonin. According to a recent theory of muscle contraction⁵ these bonds contain calcium and ATP and are cleaved by the calcium-activated actomyosin ATPase.

Thus this theory predicts that a cleavage of these bonds, following the addition of serotonin to a muscle in catch, would result in liberation of both inorganic phosphate and calcium on relaxation. Some of this calcium would be transiently available to the actomyosin system, but would soon be pumped from the sarcoplasm by a process requiring further usage of ATP.

On the basis of the number of thick filaments and the dimensions of paramyosin^{4,6}, it can be estimated that the ABRM contains approximately 3×10^{16} cross-bridges per ml. If each cross-bridge is associated with one ATP then 0.05 μ mole of ATP per gram of muscle should be split if all the cross-bridges break once. However, since the muscle lengthens steadily under constant load following the addition of serotonin, it seems likely that new transient bonds must be formed and broken a few times. Thus the ATP breakage should be in the range of 0.10–0.15 μ mole per gram. The operation of the calcium pump would lead to an additional breakdown of about 0.05 μ mole/g of ATP⁷. In addition to the increase of inorganic phosphate from the breakdown of ATP, free arginine would also increase due to the subsequent action of ATP:L-arginine phosphotransferase. Experiments were, therefore, carried out to see if the predicted breakdown of ATP occurred in association with relaxation on the release of catch.

Paired ABRM were dissected according to the method of Hoyle and Lowy⁸ and loaded with 10-g weights in oxygenated sea-water at 23° C for 3 h before the experiment. The muscles were frozen in a mixture of dichlorodifluoromethane and chlorotrifluoromethane (30:70) at -176° C, and extracted for one week in 48 per cent (v/v) methanol, 0.00125 M ethylenediaminetetraacetic acid at -35° C. Inorganic phosphate was estimated by a modification of the method of Wahler and Wollenberger⁹, and free arginine determined by the method of Rosenberg, Ennor, and Morrison¹⁰ after evaporation of the methanol.

In the first experiment both muscles of a pair were preincubated in a 1 μ M serotonin sea-water solution for 30 min before stimulation with direct current. A comparison of 26 control muscles which were frozen at the peak of contraction, and the paired experimental muscles which were frozen 15 sec after the end of stimulation, showed an increase of inorganic phosphate of 0.31 ± 0.06 μ mole/g, associated with relaxation at 18° C.

In another series of experiments, relaxation by serotonin from a heavily loaded maintained catch at 10° C caused an average increase of inorganic phosphate of 0.11 ± 0.06 μ mole/g in 21 pairs of muscles.

Fig. 1 shows the results of experiments redesigned to eliminate the variance introduced by the large amount of work performed by these muscles. An unloaded muscle was stimulated with acetyl choline at 8° C and allowed to contract 30 per cent from its rest length. Further shortening was prevented by a stop. After one minute of stimulation the muscle was washed with sea-water and loaded with a 25-g weight. This was added to see if the muscle was in a good 'catch'. The criterion of a good 'catch' was taken as the ability of the muscle to hold a 25-g load for 3 min without lengthening. After 3 min the stops were removed and 30 sec later the 25-g loads were lifted from both muscles. The muscles shortened slightly during these operations due to their elastic elements. Serotonin was then added to the experimental muscle but not to the control, and after 1 min in serotonin a 10-g load was added to each muscle to see if it was in a 'catch'. The control muscle was able to bear the 10-g load but the experimental muscle returned to its rest length within 1 min. The average inorganic phosphate increase of 24 muscles which relaxed, compared with their pairs which remained in 'catch', was $+0.19 \pm 0.06$ μ mole/g ($P < 0.004$). In 8 control experiments the addition of serotonin to resting muscles caused an insignificant change in inorganic phosphate of -0.01 ± 0.05 within 2 min.

Thus there are three separate series of experiments which give the same result; namely, that about 0.2 μ mole/g

of phosphorylarginine are broken down during relaxation from the 'catch'. This value corresponds to the predicted value for the amount of ATP which should be broken down if cross-links between actin and myosin, which involve ATP and calcium, are responsible for the maintenance of tension during a 'catch'.

Investigations have also been made of the behaviour of calcium during a tonic contraction of ABRM by studying the rate of efflux of calcium-45 from four separate muscles. When the muscles were stimulated with 0.5 mM acetyl choline they developed about 200 g tension and calcium was rapidly released into the bathing solution.

After the addition of 10^{-4} M serotonin the tension fell to zero within 10 sec and there was an increased rate of calcium efflux, but the calcium was observed outside the muscle at least 5 min after the fall in tension. Therefore it seems that calcium close to the surface of the muscle is being mobilized during stimulation, but the breaking of the catch releases some calcium which is deeper inside the muscle structure and the observed efflux represents the liberated calcium which was not captured immediately by the calcium pumping mechanism. It is interesting that Woolley¹¹ found a substance in many tissues which could form a fat-soluble complex with calcium and serotonin. Thus the action of serotonin might be to sequester calcium causing a breakdown of the hypothetical links.

Fig. 1. Liberation of inorganic phosphate during release of a catch of anterior byssus retractor muscle (ABRM) following the addition of 10^{-4} M serotonin (5-HT) at 8° C. The isolated ABRM was mounted on an unloaded isotonic lever which moved between two stops. The muscle was cooled to 8° C for 5 min in sea-water gassed with nitrogen. The muscle was stimulated for 1 min with 0.5 mM acetyl choline and allowed to contract 30 per cent from its rest length. Further shortening was prevented by a stop. A 25-g load was added to the muscle and the acetyl choline removed by washing the muscle with sea-water (8° C). After a 3-min wash period the top stop was removed and the muscle contracted slightly due to its elastic elements. Thirty sec later, the 25-g load was removed and the experimental muscle surrounded by a solution of 10^{-4} M serotonin in sea-water while the control muscle was kept in sea-water. After 1 min of this treatment, a 10-g load was added to each muscle and, 60 sec later, the muscles were frozen in a mixture of chlorotrifluoromethane: dichlorodifluoromethane (70:30) at -176° C. The dashed line represents a typical kymograph tracing for the control muscle. The solid line refers to the experimental muscle.

The finding that there is a release of inorganic phosphate, arginine, and calcium on sudden relaxation from a tonic contraction is consistent with the hypothesis that a specific type of cross-link between actin and myosin is responsible for the prolonged maintenance of tension in the ABRM. Loss of tension requires the cleavage of those links with liberation of inorganic phosphate and calcium. These findings would not be expected from a phase transition of paramyosin³ or if the linkage were of the type suggested by Perry¹² for the interaction of actin and myosin.

We thank Mrs. Constance J. Kick for her assistance and Dr. Jean Hanson for advice.

HAEMATOLOGY

Hereditary Ovalocytosis and Haemoglobin E-Ovalocytosis in Malayan Aborigines

THE red blood cells of mammalian vertebrates, including man, are normally round, except those of the camel, which are characteristically oval in shape. Less than 15 per cent of the red blood corpuscles in normal healthy men are oval, but in severe anaemias the number of oval cells in the peripheral blood may become much higher. This symptomatic ovalocytosis in severe anaemias is to be distinguished from hereditary ovalocytosis, or elliptocytosis, first described by Dresbach¹ in 1904. In the hereditary condition, more than 25 per cent of the red blood cells are oval or elliptic, and elliptic rod-shaped cells are more common than in the symptomatic condition. The two conditions can usually be distinguished, with experience, but the diagnosis can only be confirmed by demonstration of a family occurrence. Incidence of the hereditary condition in the general population has previously been estimated at approximately 0.04 per cent^{2,3}, although more prevalent in Dutch, German and Italian families^{4,5}. A focus of high frequency of hereditary ovalocytosis (elliptocytosis) has been reported from central Celebes⁶. I now report another focus of high frequency of hereditary ovalocytosis (elliptocytosis) in Malayan aborigines.

Blood smears of 440 persons comprising two groups of aborigines, mostly from the Senoi tribe, were examined. A group of 152 healthy males was made up of 110 jungle fighters of the Senoi Praak regiment and 42 personnel of the Ulu Gombak Aboriginal Hospital. The other group consisted of 288 patients from the same Aboriginal Hospital. In the healthy group, 15 soldiers and 6 Aboriginal Hospital personnel were found to have ovalocytosis with many elliptic rod-shaped/red cells, while 33 of the 288 hospital patients had ovalocytosis. The total frequency was 12.3 per cent among the 440 persons.

Although, except in 2 cases, no confirmation of the family trait could be obtained, as all relatives lived in the deep jungle, this condition was believed to be hereditary, as none of the healthy group was anaemic, while many elliptic cells, rather than oval cells, were seen in the blood. Frequency of this abnormality in the aborigines was in marked contrast to findings among 150 healthy individuals of different non-aboriginal races in Malaya, none of whom had ovalocytosis of the blood. Among patients from the General Hospital at Kuala Lumpur referred to the Haematology Division of the Institute, mostly for anaemia, 990 were examined for their peripheral

blood picture and only three (two Malays and one Chinese) were found to have hereditary ovalocytosis, confirmed by study of the family trait. This hospital serves Chinese, Indians and Malays. Although many of the patients suffering from anaemia were found to have numerous oval cells in the blood, these were readily recognized as symptomatic and could be differentiated from the aboriginal ovalocytosis.

Since the aborigine has a high frequency of the gene for abnormal haemoglobin E, ranging between 8 and 50 per cent in different groups⁷, it is to be expected that the new genetic combination of the gene for ovalocytosis with the gene for haemoglobin E, not reported until now, is not rare in this population. Indeed, of 18 cases of ovalocytosis among healthy aborigines, whose haemoglobins could be analysed, I found 2 associated with haemoglobin E in the blood, and of 22 cases of ovalocytosis among Aboriginal Hospital patients whose blood was examined for abnormal haemoglobin, 4 carried haemoglobin E. Attempts are being made to examine the families, and results of full haematological studies will be reported elsewhere in collaboration with Dr. J. M. Bolton of the Aboriginal Hospital, Ulu Gombak.

I thank Mr. Mohamed Ruslan bin Abdullah and Mr. Abdullah bin Sain of the Senoi Praak Regiment for their co-operation, and Dr. J. M. Bolton of the Aboriginal Hospital for his assistance.

I Antigen in Leukaemic Patients

P. J. SCHMIDT *et al.* have observed 20 diminutions or disappearances of I antigen in 20 patients out of 116 investigated cases¹. Among these, 15 were suffering from various forms of chronic or acute leukaemia.

We for our part have observed, following many authors, ABO modifications in various leukaemic patients^{2,3}. We have also observed a decrease of inhibiting power of Gm factors in these diseases. Table 1 shows our results. We should point out, however, that these modifications are almost always observed in patients suffering from acute leukaemia.

Table 1. BLOOD GROUP MODIFICATIONS IN LEUKAEMIAS

System	No. of cases	No. of modifications
Gm	79	6
ABO	66	1 (A) and 3 (H)
Rh	62	0

We have also investigated I antigen in healthy subjects and leukaemic patients. Our results (Table 2) indicate that we have not observed a decrease of I antigen in the

patients which we investigated. The anti-I antibody which we used was obtained from a subject who, to all appearances, was healthy and was I-positive. The research on I antigen was made possible by the use of the technique of tube agglutination; for all our leukaemic patients, a control was effected by a titration method which enabled us to determine quantitatively any variations in the I antigen.

Table 2. DISTRIBUTION OF I ANTIGEN

	No. of cases	I-positive	I-negative
Blood donors	10,090	10,089	1
Patients	2,250	2,250	0
Leukaemias	56	56	0

Our results differ from those of P. J. Schmidt *et al.*

We are still carrying out our investigations and hope to throw some light on the origin of these differences.

We thank Dr. A. E. Mourant (Lister Institute, London) for controlling the specificity of this anti-I serum.

Involvement of the Adrenal Cortex in the Appearance of Rat Slow Alpha₂-Globulin

SLOW α_2 -globulin (SA₂G) is a protein which can be demonstrated by vertical starch-gel electrophoresis to be present in the blood serum of the rat in certain physiological, pathological and experimental situations: during pregnancy¹⁻³ and lactation³, in the foetal^{1,3,4} and neonatal¹⁻⁴ states; in rats bearing growing neoplasms^{1,2,5}; in the presence of infections or inflammations⁶; after partial hepatectomy^{7,8}, splenectomy or unilateral renal-ectomy⁹; and following the administration of carbon tetrachloride⁷, various bacterial lipopolysaccharides (endotoxins)^{10,11}, complete or incomplete Freund's adjuvant¹¹, turpentine¹², or certain metallic salts¹³. It generally cannot be demonstrated by this technique, however, in healthy, non-pregnant adult rats¹⁻⁴, nor after clean laparotomies⁷, partial limb amputations⁹, or heavy doses of ionizing radiation¹⁴. Consequently, we define the SA₂G effect as being the appearance of demonstrable levels of SA₂G in response to a competent stimulus. In view of the broad range of competent stimuli for the SA₂G effect, a search for a common factor or controlling agent was undertaken. The present work indicates that the adrenal cortex is intimately involved in the appearance of the SA₂G effect provoked by at least one of the competent stimuli and may be a controlling factor.

Animals used, general procedures and vertical starch-gel electrophoresis were as previously described³. Lipopolysaccharide (endotoxin) of *Salmonella abortus equi*¹¹ (Westphal method, Difco Laboratories, Detroit, Michigan) was used as the provoking agent. Bilateral adrenalectomy was performed through a single skin and double muscle incision under ether anaesthesia. Immediately after the operation the animals were given 0.8 mg of corticosterone (Nutritional Biochemicals Corporation, Cleveland, Ohio) subcutaneously. The sham operation (group 9, Table 1) was performed in a manner analogous to the adrenalectomy. As a general protocol, no further treatment was given until the 20th day after the operation except that all animals were given 1 per cent sodium chloride solution in place of drinking water from the operation onward. The same substitu-

tion was also made for all unoperated animals at least 21 days prior to the injection of lipopolysaccharide or the control dose of saline solution. Animals in groups 2, 3, and 7 were given 0.5 mg lipopolysaccharide in 0.05 c.c. physiological saline intraperitoneally on the 21st post-operative day. Animals in groups 1 and 6 were given the same dose, but not subjected to operation. Animals in groups 4, 5, 8, and 9, serving as controls, were injected intraperitoneally with 0.05 ml. of plain physiological saline. In groups 3, 4, 5, and 6, 1.0 mg corticosterone in 0.5 ml. of physiological saline was injected twice daily, beginning one day prior to the injection of lipopolysaccharide or saline and continuing through the 5th day after injection of lipopolysaccharide or saline. Animals in group 7 were given daily injections of 0.5 ml. physiological saline in the same manner as those treated with corticosterone. Serum samples were obtained from all animals and examined for SA₂G content 2 days after injection of the lipopolysaccharide or the corresponding saline control injection. Some samples were obtained and examined at 4 or 6 days after injection and the results obtained were in consonance with those from the second post-injection day.

Table 1. EFFECT OF ADRENALECTOMY AND REPLACEMENT THERAPY ON THE ABILITY OF BACTERIAL LIPOLYSACCHARIDE TO PROVOKE DEMONSTRABLE SLOW α_2 -GLOBULIN

Group	Adrenal-ectomy	0.5 mg lipopolysaccharide injected (a)	0.05 ml. saline injected (a)	Corticosterone injected (b)	Saline injected (c)	No. of rats examined	% of rats showing SA ₂ G response
1	-	+	-	-	-	16	81.3
2	+	+	-	-	-	10	0
3	+	+	-	+	-	10	70.0
4	+	-	+	+	-	7	14.3
5	-	-	+	+	-	8	0
6	-	+	-	+	-	8	37.5
7	+	+	-	-	+	8	25.0
8	+	-	+	-	-	7	0
9	(d)	-	+	-	-	10	0

(a) Injected 21st post-operative day into adrenalectomized animals, and 1st day into control animals.

(b) 1 mg corticosterone in 0.5 ml. saline injected twice daily beginning one day prior to injection of lipopolysaccharide or saline.

(c) 0.5 ml. saline injected twice daily beginning one day prior to injection of lipopolysaccharide.

(d) This group was sham operated.

Because adrenalectomized animals have very little resistance to the effects of bacterial lipopolysaccharides, it was necessary to use a much smaller dose than in previous work¹¹. Nevertheless, the 0.5-mg dose used here (group 1) is a competent stimulus for the SA₂G reaction in approximately 81 per cent of the animals. In none of these animals was SA₂G still demonstrable 6 days after injection. The results of group 2 show that, in the absence of the adrenal gland, the effectiveness of the lipopolysaccharide as a stimulus for the SA₂G reaction is abolished. This loss of responsiveness following adrenalectomy is largely reversible by the administration of corticosterone as shown by the results of group 3 where 70 per cent of the animals had demonstrable levels of SA₂G. Corticosterone itself is not an effective stimulus for the SA₂G reaction whether administered to adrenalectomized (group 4) or non-adrenalectomized (group 5) animals. The administration of both corticosterone and lipopolysaccharide to non-adrenalectomized animals (group 6) leads to an equivocal result. The number of animals reacting is considerably below that of non-adrenalectomized animals given only lipopolysaccharide (group 1) but above that of adrenalectomized rats treated with the lipopolysaccharide (group 2). That the re-appearance of the SA₂G reaction after administration of corticosterone is not a spurious effect, due to the sodium chloride injected with it, is shown in the results of group 7 where, despite the administration of equivalent amounts of sodium chloride, substantially no restoration of the SA₂G effect was found. The results obtained with this group of animals reinforce those obtained in group 2. Finally, groups 8 and 9 indicate that the mere injection of saline into either an adrenalectomized or a sham-operated animal does not provoke the SA₂G reaction.

It would appear, therefore, that:

(1) Adrenalectomy greatly reduces or abolishes the SA₂G reaction.

(2) This reaction can be restored, at least in part, by replacement therapy using corticosterone.

(3) Corticosterone, while having some effect on the SA₂G reaction, does not itself provoke the reaction.

We conclude from this that the adrenal gland, and presumably the adrenal cortex, is intimately involved in the SA₂G reaction to bacterial lipopolysaccharide, that is, that response of the rat to the administration of bacterial lipopolysaccharide which results in the production of demonstrable levels of SA₂G. We are now attempting to determine whether the involvement of the adrenal gland is a special case in relation to the stimulus used here or whether it represents a common factor in the SA₂G reaction regardless of the nature of the stimulus used.

HISTOCHEMISTRY

Vital Staining of the Granulated Juxtaglomerular Cells in the Mouse Kidney

THE first reports on vital staining of the granulated cells of the juxtaglomerular system (JG) came from Japanese research workers. Sugiyama¹ used neutral red intravitaly to demonstrate these cells in the kidney of the mouse. Harada² used neutral red and trypan-blue intraperitoneally; paraffin-embedded sections of the kidney were examined after treatment with a bichromate containing fixative. Of the two dyes studied, only the neutral red stained the JG cells.

No data are available as to whether or not other dyes are suitable for staining these cells vitally. In squashed sections of mouse kidney the granulated cells of the preglomerular arteriolar walls are easily detected because of the brilliance of their granules (Fig. 1). Vital staining of these cells can be studied thus in native specimens, without using fixatives, embedding or sectioning.

Adult albino mice of both sexes were used for the experiments. Thirty-eight dyes related to azine, oxazine, thiazine, azo, diazo, phenylmethane and xanthen were used. These were used as 1 per cent solutions, dissolved in physiological saline, and given intraperitoneally and intravenously in 1 ml. volumes. Animals were killed immediately after intravenous injections and 30–60 min after intraperitoneal administration. After killing, squash specimens were immediately prepared from the kidneys; they were examined under a light microscope, and after treatment with acridine-orange by means of fluorescence microscopy (Fig. 3).

Cells of the reticulo-endothelial system and of renal tubuli take up and store acid dyes preferentially³. The JG cells do not take up vitally acid dyes. Positive vital staining was achieved of the JG cells by neutral red-brilliant-cresyl-blue, Nile-blue-sulphate and acriflavine, orange. Staining was most pronounced when the dyes were immediately applied intravenously and also when they were applied intraperitoneally after 1 h (Fig. 2). Some of the dyes tested proved to be toxic. For example, intravenous applications of brilliant-cresyl-blue killed the animals instantly, but the JG cells stained well.

As regards any vital staining mechanism, two factors have to be taken into account: (i) the membrane permeability of the dye; (ii) the physical or chemical affinity of the dye to the granular material.

The membrane permeability of a dye depends on its molecular weight, lipid solubility, and the number of the free methyl groups⁴. The aforementioned four dyes are of basic character, lipid-soluble and possess 2–4 free methyl groups, while the molecular weights vary between 288.7 and 732.8. Seven further basic, lipid-soluble dyes (namely, neutral violet, safranin, azure II, Janus green, gentian violet, crystal violet, Victoria blue) were also attempted. They possess 3–6 free methyl-groups, and their molecular weights vary between 364.8 and 511. As regards membrane permeability, on the whole, they are similar to the aforementioned four dyes; nevertheless they were un-

Fig. 1. Squash section of a mouse kidney. The epithelioid cells of the arteriolar wall contain strongly refractile granules. The glomerulus is indicated by arrows. ($\times 1,000$)

Fig. 2. Squash section prepared immediately after intravenous injection of neutral red. The epithelioid cells contain a large amount of red granules. ($\times 600$)

suitable for inducing vital staining in the granules of the JG cell.

As regards the affinity of the dyes for the JG cells, we have few data to rely on. The staining ability of neutral red was explained by Harada² as being due to the presence of a polysaccharide-sulphate-ester-lipid complex in the granules (Feyrter's chromotrope lipid).

According to Gomba, Soltész and Endes^{5,6} in the granules, neither lipids nor acid polysaccharides were demonstrated histochemically, while large amounts of aromatic amino-acids were found (especially tryptophan and tyrosine). In staining plant cells with neutral red, Boyer⁷ directed attention to the importance of trihydroxyphenols in binding the dye. In animals, similar compounds do not occur, and the connexion between staining of the JG granulated cells and their content of aromatic amino-acids is questionable.

Fig. 3. Squash section prepared 1 h after intraperitoneal injection of acridine orange. The granulated JG cells show a bright yellowish fluorescence. ($\times 200$)

The mechanism of vital staining by alkaline dyes may be explained by the production of salt-bonds between the basic dye and acid cellular parts. With the four dyes, besides the granulated JG cells mast cells were also stained. These cells are known to contain a high concentration of acid groups. According to Strugger⁸ the relation of the isoelectric point of the staining structure to the pH of the medium is important. This relation determines dissociation, that is, the reactive condition of the acid groups in the staining structure. In fixed specimens, the granules of the JG cells are intensively basophilic, which suggests the presence of acid groups. No explanation can be offered, however, for the inability of other alkaline, lipid-soluble dyes, similar in molecular weight and number of free methyl groups to the aforementioned four successful ones, to stain vitally.

IMMUNOLOGY

Thymus and the Production of Antibody-plaque-forming Cells

ALTHOUGH the thymus itself does not play an active part in immune responses¹, its presence is essential for the normal development of immunological faculties. Neonatal thymectomy in many species considerably impairs the capacity of an animal to produce some types of immune responses². Thymectomy in adult life has no immediate effect but, after a period of 6-9 months, reduces the capacity to react to a newly encountered antigen³. The possible mechanisms by which the thymus exerts its influence on the immunological system have been discussed elsewhere⁴, and it has been concluded that the immunological defects encountered after thymectomy are primary and not secondary to infection or auto-immunity⁵. Evidence is presented here to show that thymectomy practically inhibits the development of the capacity to produce antibody-plaque-forming cells following the injection of sheep erythrocytes. This impairment is evident in clinically healthy suckling baby mice thymectomized at birth.

Mice of the inbred strain CBA, F_1 hybrids from crosses between T6 and Ak mice, and non-inbred Swiss (SWS) mice were thymectomized on the day of birth. A sham operation involving thoracotomy, but not removal of the thymus, was performed in litter-mates. The mice were given an intraperitoneal injection of 0.15 ml. of a 5 per cent suspension of sheep erythrocytes in saline on the 10th day of life and killed at intervals of 2 days-3 weeks after injection. Cell suspensions were prepared from their spleens and assayed for the number of antibody-plaque-forming cells by plating out the suspension in agar gel containing sheep erythrocytes according to the technique described by Jerne *et al.*⁶. Routine histological investigations were performed on the thymus area in all thymectomized mice to ensure that thymectomy had

been complete. Mice with thymus remnants were discarded from the experiments.

The spleens of normal or operated mice aged between 1 week and 4 months and not challenged with sheep erythrocytes gave usually less than 1 antibody-plaque-forming cell per million spleen cells. The results obtained in immunized mice are shown in Figs. 1, 2 and 3 and analysed statistically in Table 1. In sham-thymectomized mice, the number of antibody-plaque-forming cells rose sharply from 2 to 3 days after immunization to reach a peak level at 4, 5 or 6 days, depending on the strain. Thereafter, the number fell rapidly to reach a low, yet significant, level at about 10 days after immunization. By contrast, neonatally thymectomized mice produced very few antibody-plaque-forming cells, the assays being made at intervals from 2 days to 3 weeks after challenge. The difference between the mean peak levels of the thymectomized and control group was highly statistically significant for the three strains of mice used (Table 1).

Thymectomy of 6-weeks-old SWS mice did not interfere with their capacity to produce antibody-plaque-forming cells when immunized at about 9 weeks of age (Table 1). In contrast to the spleens of normal SWS mice immunized with sheep erythrocytes, very few antibody-plaque-forming cells were present in the thymuses of the same mice (Table 1).

The results demonstrate that, in the absence of the thymus from birth, the capacity to produce antibody-plaque-forming cells in response to an injection of sheep erythrocytes has failed to develop. Very few antibody-plaque-forming cells appeared in the spleens during the first 3 weeks after immunization of neonatally thy-

mectomized mice of two inbred strains and one non-inbred stock. This deficiency is presumably a primary effect of neonatal thymectomy and not secondary to infection or ill-health: it was evident in very early life in suckling baby mice the growth rate of which was identical to that of litter-mate controls. In a similar experiment it has been reported that colony-bred mice thymectomized at birth also failed to produce normal numbers of antibody-plaque-forming cells when challenged at 4 weeks of age⁷. Thymectomy in adult mice, by contrast, had no immediate effect on the response to sheep erythrocytes although a delayed effect was observed as reported elsewhere⁸. The amount of antibody produced per plaque-forming cells was judged to be within normal limits in the thymectomized mice as estimated by the size of the plaques in our experiments and in those of Takeya *et al.*⁷.

It can be seen that the thymus itself produced only very few antibody-plaque-forming cells (Table 1) after immunization of adult mice. This observation has also been made in other strains of mice⁸. By contrast, specific antibody-plaque-forming cells have been demonstrated in the thymus of rabbits 5 days after a single systemic injection of 5 μ g of somatic polysaccharide of *Salmonella enteritidis*⁹. Since significant numbers of plaque-forming

cells have been detected in the peripheral blood in these rabbits¹⁰, and since radical alterations in the structure of the thymus have been reported after administration of endotoxin¹¹, it is conceivable that circulating antibody-forming cells may have penetrated into the thymus of rabbits immunized with somatic polysaccharide.

In conclusion, it seems that the thymus itself fails to produce significant numbers of antibody-producing cells in response to an antigenic stimulus, but its presence from birth is essential to ensure that such cells will develop in the periphery. Whether the initial development of these cells takes place within the thymus and their final maturation occurs after emigration from the organ cannot be decided on the basis of present evidence. Experiments using thymus tissue enclosed in cell-impenetrable chambers in neonatally thymectomized mice have suggested that a humoral thymus factor plays a part in the maturation of potentially immunologically competent cells¹².

Decay of Immunological Responsiveness after Thymectomy in Adult Life

THE remarkable effects of neonatal thymectomy are by now well documented¹. Primary among these is a failure of the lymphoid tissues to develop properly, which is marked particularly by a deficiency of small lymphocytes. Other features, probably resulting from this, include a defective capacity to perform all kinds of immune responses, and a progressive wasting disease ending in early death.

By contrast, only minimal effects have been found to follow from thymectomy in adult life. In mice, the operation had no effect on growth rate, breeding behaviour, longevity or susceptibility to common infections², although blood lymphocyte counts and lymphoid organ

weights were somewhat depressed³. A wasting disease has been reported in guinea-pigs thymectomized at 150–160 g body-weight⁴. No significant depression of antibody response has been detected after thymectomy of adult rabbits^{5,6}. These results have led to the assumptions that once the lymphoid tissues have been formed, the thymus ceases to perform in its developmental role, and that the function of lymphopoiesis is then taken over by the other lymphoid tissues⁷. Yet no distinct morphological change has been described in the thymus on the attainment of immunological maturity, and it continues its high rate of cell production even in adult life. Indeed, it is still necessary for the recovery of immunological responsiveness after this has been depressed by irradiation⁸, and thus it must be able to resume its lymphopoietic function, if only in response to a stimulus such as might be provided by destruction of lymphoid tissues. Even without this stimulus, however, the thymus must play some part in normal turnover of lymphoid cells, since thymectomy in adult life largely prevents recovery from immunological paralysis^{9,10}. It therefore seemed probable that the lymphoid tissues might not be able to maintain themselves indefinitely in the absence of the thymus, and that if mice were left for a sufficiently long time after thymectomy in adult life they should eventually show a decline in their primary immune responsiveness.

In the first experiment the immune responsiveness of CBA mice was assessed by the ability of their lymphoid cells to cause a graft-versus-host (GVH) reaction after transfer to young (C57BL × CBA)_F₁ hybrid mice. The strength of the GVH response was estimated by the degree of spleen enlargement in the hosts. The 4-point assay procedure outlined by Simonsen¹¹ and developed by Michie¹² was then used to relate the spleen enlargement response to the dose of lymphoid cells, so that a quantitative comparison could be made of the immune potency of cell suspensions made from thymectomized and control mice. CBA female mice were thymectomized (or sham-operated) at 2–3 months of age. Groups of 8–16 mice were tested by GVH assay at intervals up to one year after thymectomy. In each assay the pooled lymph node (cervical, axillary, brachial, inguinal and mesenteric) and spleen cells of one 'test' mouse were compared for immune potency against those from one 'control' mouse. At the intervals 4, 9, 25 and 29 weeks the thymectomized mice were compared with sham-operated controls of the same age. By 52 weeks the potency of these controls might be expected to have declined somewhat through age alone¹³; therefore both thymectomized and sham-operated mice were compared with untreated controls aged 4–6 months. To obtain a measure of the overall responsiveness of the whole 'test' animal as a percentage of the control, each value for the relative potency of a cell suspension was multiplied by the fraction: total number of lymphoid cells obtained from the 'test' mouse/total number of lymphoid cells obtained from the 'control' mouse.

The results of the assays are shown in Fig. 1. The responsiveness of the thymectomized mice remained level with controls for about 25 weeks, then dropped fairly sharply, and thereafter remained about 15 per cent of normal. This fall in responsiveness was due mainly to a fall in the immune potency of the cell suspensions, but also to a fall in the numbers of cells recovered. The responsiveness of sham-operated mice fell only slightly, and at 52 weeks after operation was still about 75 per cent of the 4–6-month-old controls.

In another experiment immune responsiveness was tested by the ability to produce circulating antibody to bovine serum albumin (BSA). The results have been collated from four experiments which were set up with other primary objects in mind. CBA mice of both sexes were thymectomized or sham-operated either at 4 weeks or at 10–14 weeks of age. They were challenged at intervals thereafter by subcutaneous injection of BSA in Freund's adjuvant, and the serum antibody titres estimated 20

and 40 days later by a modification¹⁴ of Farr's antigen-binding-capacity method¹⁵. Since the absolute titres varied from one experiment to another, the titres from thymectomized mice have been presented as a percentage of the controls in each group (Fig. 2). The decay of responsiveness was less obvious than it was in the GVH experiment, but cell-transfer experiments indicate that a small difference in anti-BSA titre can reflect a larger difference in the number of competent cells¹⁶. However, the general pattern was similar in that the decline did not reach its most rapid phase for a considerable time after thymectomy. (The apparent initial fall which can be seen in the mice thymectomized at 4 weeks old reflects an increase in the responsiveness of controls, due to normal growth processes, rather than a decrease in the thymectomized mice.) This rapid phase can be seen at about 10 weeks after thymectomy in the mice thymectomized at 4 weeks old. In those thymectomized at 10–14 weeks old the time varied: in one experiment the responsiveness was still normal at 16 weeks, but in another it had already reached its lower level by 12 weeks after thymectomy (indicated by asterisk) and showed no further fall at 32 weeks. An effect of thymectomy was also seen in the general condition of the mice. While not amounting to a serious wasting disease, it appeared as a distinct ruffled condition of the fur, most obvious on the underside, and was associated with a slight loss of weight.

It may be concluded that even in the adult the thymus has a part to play in the maintenance of the numbers of competent cells in the body. If the effect of thymectomy was to cut off entirely the supply of new competent cells, then the ensuing decay of responsiveness should reflect the rate of loss of the competent cells originally present. According to two simple hypotheses their numbers might be expected to decay in linear fashion if they had a definite life-span, or exponentially if their life depended on chance events—such as encounter with antigens. Support for the latter possibility may be drawn from investigations of irradiated human patients¹⁷ in whom certain of the circulating lymphocytes were distinguishable by the presence of acentric chromosome fragments, which could be seen after stimulation of mitosis *in vitro* with phytohaemagglutinin. During division these fragments fail to become attached to the mitotic spindle, and thus are not transmitted to the daughter cells. The half-time between irradiation and either division or death of the cells was 366 days.

In the present experiments, however, the decay curve of immune responsiveness after thymectomy did not readily fit with either expectation (Fig. 1). In particular,

Fig. 1. Results of GVH assays. Each point represents the mean and standard deviation of the responsiveness of thymectomized relative to control mice (computed on log-transformed data). ●, Thymectomized versus sham-operated controls of the same age (4–29 week groups) or versus 4–6 month untreated mice (52-week group); ○, sham-operated (14 months old) versus 4–6 month untreated mice. $P < 0.01$ for difference between 25 and 29 week groups; $P < 0.001$ for difference between thymectomized and sham-operated groups at 52 weeks. Hypothetical linear (—) and exponential (---) decay curves are shown.

Fig. 2. Results of antibody titrations. Each point represents the mean antibody titre in thymectomized mice as a percentage of that in controls, with standard deviation (computed on log-transformed data). Results from 20 and 40 day bleedings have been combined. Symbols represent four separate experiments: ○, thymectomized at 4 weeks old; ●, thymectomized at 10–14 weeks old. * See text.

although the responsiveness fell to a sub-normal level, it appeared to attain equilibrium by about 7 months after thymectomy, and showed no further decline towards the levels seen after neonatal thymectomy or irradiation. The same was shown by at least one of the BSA experiments (Fig. 2, asterisk). This suggests either that there is a distinct population of cells with a very long life, or that the production of competent cells can continue at a sub-normal rate in the absence of the thymus. In view of the much more severe and permanent depression of responsiveness which can be obtained after neonatal thymectomy, or adult thymectomy followed by irradiation, this latter process would presumably take place only in mature, unirradiated lymphoid tissue.

Although the early part of the curve approximates the linear, rather than the exponential mode of decay, it might still be consistent with an exponential loss of cells if these were being replaced by differentiation from some other cell type. This could be an intermediate form which had already undergone the thymus-dependent phase in its maturation. The eventual exhaustion of such cells could then account for the more rapid fall between 25 and 29 weeks. In conclusion, it is suggested that the thymus continues in adult life to exert a stimulatory influence on the production of competent cells, but that a low rate of production may still occur after thymectomy. It will be of interest to see if this residual responsiveness differs qualitatively from the major fraction, which decays more rapidly after thymectomy.

Delayed Effect of Thymectomy in Adult Life on Immunological Competence

NEONATAL thymectomy leads to the rapid development of lymphoid organ atrophy and well-characterized immunological deficiencies¹⁻³, but thymectomy performed in adult life leads only to the slow development of a moderate degree of lymphoid atrophy⁴ with no loss of immunological competence when the animals are tested immediately after operation^{5,6}. However, adult thymectomy combined with whole-body irradiation does lead to immunological deficiencies of the same general nature as those following neonatal thymectomy⁷. Recent investigations have shown that continuous repopulation of normal haemopoietic organs occurs in normal life^{8,9}. This suggests that whole-body irradiation by causing cell damage and repopulation in haemopoietic organs may merely accelerate a process which occurs continually throughout life, albeit at a much slower rate. These considerations prompted a re-examination of the long-term effects of adult thymectomy on immunological competence.

Six-week-old mice of the long-lived (*AKR* × *C57BL*)_F₁ strain were thymectomized or sham-operated and challenged 1 week, 11 months or 18 months after operation with intraperitoneal sheep red cells.

Fig. 1. Haemagglutinin titres in (*AKR* × *C57BL*)_F₁ mice tested 11 months after thymectomy or sham-operation at six weeks of age. No. of mice: thymectomy 23, sham-thymectomy 31. Bars represent standard deviations.

The present results re-emphasize that the thymus has a continuing influence on immunological responsiveness throughout adult life, but do not indicate the processes

Table 1. PRIMARY HAEMAGGLUTININ RESPONSE OF (*AKR* × *C57BL*)_F₁ MICE TO SHEEP RED BLOOD CELLS

Type of mouse	No. of animals	Haemagglutinin titres (log ₁₀)										
		0	1	2	3	4	5	6	7	8	9	10
Normal 2 months old. No antigen	14	12		1			1					
Normal 18-20 months old. No antigen	18	18										
Thymectomy + antigen. 1 week after operation	13											
Sham-thymectomy + antigen. 1 week after operation	14											
Thymectomy + antigen. 11 months after operation	23			1		3	2	6	10	1	6	3
Sham-thymectomy + antigen. 11 months after operation	31											
Thymectomy + antigen. 18 months after operation	13	6	1				2	1	13	13	3	1
Sham-thymectomy + antigen. 18 months after operation	48				4	4	4	7	11	12	3	2

Immunizing dose: 0.2 ml. of 20 per cent R.B.C. i.p. Sera titrated on day 10 following immunization.

Haemagglutinin titres in mice challenged immediately after thymectomy did not differ from those in control mice (Table 1). However, in mice tested 11 months after thymectomy, some lower titres were found, particularly in the early (19S) phase of the response (Fig. 1). In mice tested 18 months after operation, approximately half the thymectomized mice produced no detectable haemagglutinins (Table 1), the remainder producing titres within the control range. The titres in the thymectomized mice challenged 18 months after operation corresponded almost exactly with those observed by Miller⁷ in young adult mice subjected to thymectomy and 350-r. whole-body irradiation. The spleen is the major source of haemagglutinin-production (Metcalf, unpublished results) and in the immunized thymectomized mice challenged 18 months after operation, a general disorganization of the structure of the spleen lymphoid nodules was observed with an obvious decrease in the numbers of germinal centres and small lymphocytes and a diminished number of pyroninophilic mitotic cells.

The observations recorded here suggest that simple thymectomy performed on adult mice does lead to demonstrable immunological deficiencies in at least some mice, provided sufficient time is allowed to elapse before the animals are tested. The present results are only preliminary and need confirmation with other mouse strains and other antigens. The irregular nature of the loss of immunological competence in individual mice following thymectomy, suggests a deletion or loss of responsiveness in some mice of clones of cells capable of responding to the antigen used, this loss apparently being on a random basis and time dependent.

The thymus is known to produce the humoral factor L.S.F. throughout life¹⁰ and a humoral influence of the thymus has been shown to be necessary for the full responsiveness of competent cells following antigenic stimulation^{11,12}. Since there is continuous spleen and lymph node cell repopulation throughout life, the thymus could also serve as a production site for immunologically competent cells, continually reseeding the peripheral organs.

Effect of Thymectomy in Adult Mice on Immunological Responsiveness

THYMECTOMY in adult animals has been associated with a lowering of the population of lymphocytes in blood, thoracic duct lymph, lymph nodes and spleen^{1,2}. However, no significant defects in the capacity for rejecting allogeneic skin homografts² or for producing serum antibodies^{2,3} have been observed in animals thymectomized in adult life and challenged within 1-2 months after thymectomy. This is in marked contrast to the severe immunological defects which occur following neonatal thymectomy⁴. These observations have suggested that, during early life, the thymus is essential for the complete and normal development of some immunological faculties. Evidence that the function of the thymus in initiating immunogenesis is not necessarily restricted to early life has, however, been produced. Adult mice thymectomized and afterwards exposed to total body irradiation have shown severe deficiencies in immunological functions^{5,6} indicating that the thymus in the adult is still essential to re-establish immune mechanisms when the immunological apparatus has been damaged or destroyed. It has been shown, furthermore, that thymectomy in adult immunologically tolerant mice prevented the reappearance of reactivity with respect to that antigen⁶. The thymus in the adult would thus appear to be essential for the correction of specific immunological defects. The work described here gives further evidence for a continuing immunological function of the thymus through adult life.

from a given donor to produce a graft-versus-host (GVH) reaction was determined by Simonsen's method of spleen assay⁸. The relative spleen weight (mg spleen/10 g body-weight) of the injected baby mice was determined at 10 days of age. Spleen indices were calculated by dividing the average relative spleen weights of the cell-injected mice by the relative spleen weights of the litter-mate controls. The average spleen index of 36 control mice was 1.00 ± 0.13 and animals with indices ≥ 1.5 were considered to show definite evidence of a GVH reaction. The results shown in Table 2 indicate that lymphoid cells from thymectomized mice are as effective as cells from control mice in producing a GVH reaction when collected up to 6 months after thymectomy. After a period of 6-9 months, cells from only 4 of 14 thymectomized mice were effective. Cells from 3 of 8 sham-thymectomized mice aged more than 1 year were ineffective in producing a GVH reaction possibly as a result of the decline of immunological capacity which occurs with advancing age⁹. In the thymectomized group, cells from only 2 of 16 mice killed 9-14 months after thymectomy produced signs of GVH reaction.

Histological examination of the spleen and lymph nodes of old thymectomized animals revealed a striking depletion of cells in the periarteriolar lymphocytic sheaths and primary lymphoid follicles.

It is now well established that some small lymphocytes are long-lived cells¹⁰ capable of initiating graft-versus-host reactions and possibly other types of immunological reactions¹¹. The results presented here demonstrate that thymectomy of adult mice is associated with a decline in

Table 1. EFFECT OF THYMECTOMY IN ADULT LIFE ON THE PRODUCTION OF ANTIBODY-PLAQUE-FORMING CELLS IN THE SPLEEN

Strain	Treatment at 2-3 months	Age (months) at immunization	No. of mice	No. of mice * showing following No. of antibody-plaque-forming cells per 1,000,000 spleen cells:				
				0-100	101-300	301-500	501-800	801-1,200
<i>(Ak × T6)F₁</i>	Sham-thymectomy	4	5					5
	Thymectomy	4	6					6
<i>CBA</i>	Sham-thymectomy	9	6					6
	Thymectomy	9	8			6	2	4
	Sham-thymectomy	4	4					4
	Thymectomy	4	4					4
	Sham-thymectomy	18	5			1	4	
	Thymectomy	18	7	1	4	1	1	
	Sham-thymectomy	24	3			2		
	Thymectomy	24	3	3				

* Killed at time of peak titre after immunization.

In one experiment inbred *CBA* mice and *(Ak × T6)F₁* mice were thymectomized at 2-3 months of age and challenged at various intervals up to 2 years after thymectomy with 0.3 ml. of a 5 per cent suspension of sheep erythrocytes in saline. 4-6 days after challenge, the mice were killed and their spleens removed to assay the number of antibody-plaque-forming cells per million spleen cells, according to the technique described by Jerne *et al.*⁷. Lymph nodes, a small part of the spleen and the thymus area were also removed and kept for histological examination. The results of the plaque assays are shown in Table 1. There was no difference in the capacity of thymectomized and sham-thymectomized mice to produce antibody-plaque-forming cells when injected with sheep erythrocytes 2 months after the operation. However, thymectomized mice challenged 9 or more months after operation produced less antibody-plaque-forming cells than controls.

In another experiment, *C3Hf/BI* mice were thymectomized or sham-operated at 2-4 months of age and killed from 4 to 60 weeks later. Cell suspensions were prepared from the spleens and mesenteric lymph nodes and 5-6 million cells in 0.05 ml. buffered Ringer phosphate solution were injected intravenously into new-born (*C3Hf × C57BL*)*F₁* mice. Half of each litter (about 3-4 mice) received the cells and the other half received only the buffered solution. The capacity of the cell suspensions

immunological capacity which becomes significant after a period of 6-9 months. They suggest that the thymus continues to function during adult life in order to maintain an adequate pool of immunologically competent cells. Thymectomy in the adult, unlike thymectomy in the new-born, has no immediate effect on immunological capacity, presumably because an adequate pool of competent cells has already been constructed. Only when the pool becomes depleted, owing to the limited life span of its cells, do immunological defects with respect to newly encountered antigens become evident.

Table 2. EFFECT OF THYMECTOMY IN ADULT LIFE ON THE CAPACITY OF LYMPHOID CELLS TO PRODUCE GRAFT-VERSUS-HOST REACTIONS

Treatment at 2-4 months	No. of mice with lymphoid cells capable of producing GVH reactions* at following periods (weeks) after operation			
Sham-thymectomy	4-25	26-40	41-60	
Thymectomy	5/8	7/8	5/8	
	12/13	4/14	2/16	

* Expressed as fraction of mice with cells producing, in new-born recipients, an average spleen index ≥ 1.5 .

Rapid Detection and Titration of Antihuman Serum Albumin Antibody

HUMAN serum albumin (HSA) is an antigen frequently used for the examination of the synthesis of antibody in various species. The techniques usually utilized are variants of either precipitin or haemagglutinating methods. Although these procedures are extremely sensitive, both suffer from the disadvantage of requiring a time-interval between the addition of reagents and final reading of the results. The haemagglutinating techniques, furthermore, require absorption, frequently multiple times, of the sera with the red cells which are used in the testing method. The following technique, a slight modification of a method described¹, has proved to be reproducible, rapid, and to have the sensitivity of tanned red cell haemagglutination. Ten ml. of bentonite stock solution prepared according to the method of Bozicevich *et al.*¹ is centrifuged at 1,800 r.p.m. for 15 min. The pellet is re-suspended in 1 ml. of distilled water and an equal volume of a 1 per cent saline solution of human serum albumin is then added. The mixture is shaken gently and permitted to incubate at room temperature for 15 min. One ml. of 0.1 per cent aqueous methylene blue and 15 ml. of distilled water is added, the suspension shaken, and after 10 min recentrifuged for 10 min. The pellet is re-suspended and washed twice in 10 ml. of distilled water. The final suspension is made up with 5 ml. with distilled water. A suspension so prepared and stored at 4° C is shaken gently before use. The flocculating characteristics are retained for periods of two weeks with no change in titre.

The agglutination procedure is performed by adding one drop of the test serum to one drop of the bentonite suspension and centrifuging for 2 min in a 'Sero-fuge'. A positive test is observed as varying degrees of clumping after gently flicking the tube, and is most easily read over a fluorescent white lamp. Titrations may be carried out using a calibrated loop containing as little as 0.025 ml. with serial transfer of the serum to be tested into 10 × 75 ml. test-tubes containing saline. A fixed volume of bentonite, for example, 0.025 ml., is added and the centrifugation carried out as previously noted. Inhibition investigations with 1 per cent albumin added first to the serum followed by the bentonite have been successful. The serum

may be tested for the presence of macroglobulin and the titre of 19 and 7S antibody estimated by the addition of 2-mercaptoethanol followed by incubation for 30 min at 37° C before adding the bentonite.

Equivalent titres of antibody are obtained when the same dilutions of antisera are compared utilizing the foregoing technique and the tanned red cell haemagglutination procedure with a microtitrator².

The technique is recommended for its simplicity and rapidity of results. Once the bentonite has been sensitized the entire titration may be performed and results obtained within a matter of minutes, thus avoiding the tedious and technical difficulties of precipitin and haemagglutination procedures. Both rat and rabbit serum have been tested and yielded satisfactory results. Other substances such as bovine and human γ -globulins have not resulted in satisfactory specific agglutination patterns. It is thus likely that the success of this simplified procedure results from propitious physico-chemical properties of human serum albumin.

PATHOLOGY

Virus-like Particles in Sub-acute Sclerosing Encephalitis

SUB-ACUTE sclerosing encephalitis (van Bogaert) is a fatal disease of the central nervous system of uncertain origin, usually affecting children and adolescents. The pathological features of this disease are diffuse inflammatory cell infiltrates in the white and grey matter, gliosis, and demyelination¹. Frequently, Type A intranuclear inclusion bodies have been observed in neurones of cases running a short clinical course (Dawson's inclusion body encephalitis) while in the more chronic cases these bodies are less frequently found. Although often a viral aetiology has been suggested, the cause of this disease remains obscure, since animal inoculations of brain tissue have been unsuccessful in transmitting the disease¹.

To our knowledge, ultrastructural investigations in this disease have not been made. This electron microscopic examination of a cortical biopsy from a case of sub-acute sclerosing encephalitis has revealed a large number of virus-like particles in the cytoplasm of astrocytes in the white matter; similar virus-like particles in the cytoplasm of neurones in the grey matter were not seen.

The patient was a nine-year-old Negro female with a fifteen-month history of progressive mental deterioration, difficulty in holding objects with her hands, difficulty with gait, slurring of speech, fine tremors, enuresis, a twelve-month history of generalized seizures and a ten-month history of precocious puberty. These were followed by progressive motor and mental deterioration and transitory migratory seizures involving various extremities and facial muscles. Her history had been that of progressive deterioration with double incontinence, inability to recognize her surroundings, and inability to control arms and hands. On physical examination she was unresponsive to all but painful stimuli. There was gross cachexia, an indwelling Foley catheter, and a naso-gastric feeding tube in place. Gross postural contractures of all four extremities were present. The head was normal size, and there was increased rigidity of the neck with no adenopathy. The pupils were equal, but did not react to light. There was

bilateral optic atrophy. The maculae were within normal limits. There was no response to threat or visual stimuli. There was early breast development and pubic hair was present.

There was gross wasting and atrophy of all four extremities with an increased spastic rigidity, right greater than left. At this time, no spontaneous movements or fasciculations of the extremities were noted. The biceps and triceps deep tendon reflexes were hyperactive and equal. The patellar and ankle reflexes were absent. The Babinski responses were positive bilaterally. Gross myoclonic movements were noted on afferent stimuli.

In the absence of macular changes and the presence of myoclonus seizures, and a fifteen-month history, a diagnosis of sub-acute inclusion body encephalitis was entertained.

A cerebral biopsy, including grey and white matter, obtained through an open craniotomy, was immediately fixed in buffered formalin and osmium tetroxide. Neuropathological examination revealed extensive loss of neurones, and infiltrates of round cells in the Virchow-Robin spaces in grey and white matter (Fig. 1). Proliferation of fibrous

and protoplasmic astrocytes was noted in the deep layers of the cortex and in the white matter (Fig. 2). In the white matter, the astroglial proliferation was extensive, the number of oligodendroglial cells was reduced, and myelin sheaths were practically absent; numerous histiocytes containing sudanophilic material were also noted. Intracellular or intracytoplasmic inclusion bodies were not observed. The leptomeninges were unremarkable.

Under the electron microscope, numerous virus-like particles were seen in the cytoplasm of astrocytes (Fig. 3). The particles were made of a central dense osmiophilic core or nucleoid, about 300 Å in diameter, surrounded by a clear halo 50 Å thick, which in turn is enclosed by a single membrane also 50 Å in thickness. The diameter of the entire particle was 500 Å which is somewhat larger than the size of Coxsackie and poliomyelitis virus (300 Å), and in the size range of the equine encephalomyelitis virus (500 Å)².

The ultrastructural features of these particles are quite similar to that of known viruses; for example, there is a striking resemblance between the fine structure of the virus of the avian sarcoma-leukosis complex as revealed by Haguenau and Beard and the bodies seen in this biopsy³. The fibrillar material in the cytoplasm of the astrocytes probably is not related to the virus-like particles since it has already been identified in other cortical biopsies where astrocytosis is prominent⁴.

The characterization of these virus-like particles, and their role in the pathogenesis of the disease, are now being investigated.

The demonstration of particles of probable viral nature in a human disease of the central nervous system of sub-acute or chronic course is of interest since recovery of viruses has been achieved in animals suffering from chronic central nervous system diseases of degenerative or demyelinating nature, such as scrapie, visna and Aleutian disease of mink⁵. The probable role of a slow virus in the pathogenesis of chronic disease of the central nervous system of man should be re-investigated in view of the findings recorded here⁵.

Differential Inhibition of Deoxyribonucleic Acid and Ribonucleic Acid Synthesis induced in Cultured Mammalian Cells by 7:12-Dimethylbenzanthracene

THE mammalian cell genome has frequently been implicated as the specific site of chemical carcinogen-cell interaction. Notable were the findings of Brookes and Lawley¹, who demonstrated a positive correlation between the degree of binding of aromatic hydrocarbons to mouse skin DNA *in vivo* and the carcinogenic potency of these agents. Certain hydrocarbon carcinogens suppress interferon synthesis in virus-infected cells² and appear to be similar in activity to actinomycin D (ref. 3) in their ability to inhibit the replication of DNA rather than RNA viruses. The work recorded here concerns the probable specific

Fig. 1. Perivascular infiltrates of round cells in white matter. ($\times 300$)

Fig. 2. White matter. Protoplasmic astrocytes and histiocytes (pale cytoplasm). ($\times 300$)

Fig. 3. White matter. Electron micrograph from cytoplasm of an astrocyte. Numerous virus-like particles are seen, three indicated by arrows. Bundles of 70 Å thick fibrils are also seen in amplex numbers. ($\times 28,000$)

- alterations in DNA replication induced in cultured normal cells treated with low concentrations of 7:12-dimethylbenzanthracene (DMBA) soluble in the culture medium. The rates of incorporation of labelled uridine and thymidine were measured in several cell lines and correlated to the cell cycle and total DNA formation.

Unlabelled or tritiated DMBA (0.1 mg; sp. act. = 14,500 mc./mmole) dissolved in acetone was deposited in light-shielded flasks and the solvent was evaporated off over an 80° C water bath. The particles were shaken in a complete medium (CM) consisting of 90 per cent Eagle's essential medium + 10 per cent calf serum at 37° C for 72 h. After the shaking period the insoluble particles were removed by Seitz filtration, and the radioactivity was measured by liquid scintillation (^3H = 7–10.5 $\mu\text{C./ml.}$; DMBA = 0.5–0.75 μM). Cell preparations obtained from 4–5-day-old secondary monolayer cultures of mouse (BALB/c) or hamster embryo tissues were suspended either in CM alone (control) or CM + ^3H -DMBA (1.5 $\mu\text{C./ml.}$ = 0.12 μM). In alternate experiments, cells were suspended in CM + cold DMBA (0.12 μM). Replicate cultures ($2.5\text{--}4.0 \times 10^6$ cells/100-mm plastic dish) were incubated at 37° C in a humidified carbon dioxide incubator. At varying intervals duplicate dishes of cell monolayers were pulse labelled with serum free Eagle's medium, containing 1 $\mu\text{C./ml.}$ of either uridine-2- ^{14}C (sp. act. = 1 mc./mmole), thymidine-2- ^{14}C (sp. act. = 30 mc./mmole) or thymidine- ^3H (sp. act. = 13,000 mc./mmole) according to Levine *et al.*⁴. Radioactivity was determined by liquid scintillation and DNA was analysed by the diphenylamine action⁵.

In previous experiments⁶, phenol isolated DNA from ^3H -3:4-benzo(a)pyrene treated hamster kidney cells in culture had a specific activity of 37.5 $\mu\text{C./g.}$ This activity corresponded to 0.8–1.0 molecule of the hydrocarbon/DNA molecule of 20,000 nucleotide units, a value which closely approximated the binding level of ^3H -3:4-benzo(a)pyrene to mouse skin DNA *in vivo*¹. Control and ^3H -DMBA-treated mouse embryo cells pulsed with uridine- ^{14}C gave very similar incorporation rates of this nucleoside. In fact, the rate of incorporation of uridine- ^{14}C by carcinogen-treated cells (Fig. 1) was slightly elevated within the first 8 h following treatment. During this period the cell division mechanism was significantly impaired, although some cells apparently did divide and the survivors were viable, as evidenced by outgrowth on sub-culture in carcinogen-free CM.

Fig. 1. The effect of ^3H -DMBA (1.5 $\mu\text{C./ml.}$; 0.12 μM) on the incorporation of uridine- ^{14}C and of thymidine- ^{14}C by mouse embryo cell cultures. Time zero = time at which CM (alone) was removed from the monolayers (2 h) and the cultures then overlaid with either CM alone or CM + DMBA. —, CM alone; ---, CM + DMBA.

Fig. 2. Effect of DMBA (0.12 μM) on the incorporation of thymidine- ^3H by secondary hamster embryo cell cultures. —, CM alone; ---, CM + unlabelled DMBA.

In sharp contrast to a lack of inhibition of uridine incorporation DMBA induced a marked suppression on the rate of thymidine- ^{14}C incorporation (Fig. 2) within 2 h following mouse cell-carcinogen interaction. A measurement of the rate of incorporation of thymidine- ^3H into the acid-soluble and acid-insoluble fraction of hamster embryo cells growing in the presence of cold DMBA (0.12 μM) again demonstrated the very early inhibition of DNA synthesis. On the other hand, the DNA content per cell (corrected for viability by vital staining with 0.02 per cent nigrosin) was usually about 30–33 per cent higher in DMBA treated cells than in control cultures. The summarized results of three separate experiments are listed in Table 1.

Table 1. EFFECT OF ^3H -DMBA (1.5 $\mu\text{C./ML.}$) ON THE RATE OF FORMATION OF HOT TCA-EXTRACTABLE DNA BY MOUSE EMBRYO CELLS

Culture medium	Hours in culture	Cell No. $\times 10^6$ /dish	CPM ^3H -DMBA per 10^6 cells	$\mu\text{g DNA per } 10^6$ cells
CM alone	0	2.5	—	7.5
"	24	3.5	—	12.0
"	48	4.0	—	13.5
"	72	6.5	—	5.5
CM + ^3H -DMBA	0	2.5	—	7.5
"	24	1.6	3.5×10^5	16.0
"	48	1.5	2.0×10^5	19.0
"	72	1.8	2.1×10^5	8.0

A correlation can be drawn between the time of maximum uptake of chemical carcinogen in culture⁷ and the suppression of labelled thymidine incorporation in these experiments. These observations are in agreement with the findings on the *in vivo* depression of DNA synthesis by DMBA⁸. As cell division was inhibited by DMBA during the first 24 h of growth, the increase in DNA per cell suggests that the depressive activity of this carcinogen occurred in the pre-mitotic phase of growth. It is very likely that the surviving 'DMBA-cells' lose the control mechanism for DNA replication at some point between the S (DNA synthesis) and the G₂ phases of the cell cycle. It is possible that this carcinogen, in complexing with DNA, induces the formation of new primer sites which may be active in further DNA replication without cell division. The foregoing mechanism was recently proposed for the action of nitrogen mustard on cultured cells⁹.

The lack of inhibition of uridine- ^{14}C incorporation by DMBA during the first 24 h of culture does not rule out the possibility that synthesis of later formed DNA-dependent RNA would be suppressed, as shown by *in vivo* experiments¹⁰. The major questions provoked by these results are whether or not the early alteration induced by DMBA at the DNA level is involved in a

specific manner with neoplastic transformation, and whether this DMBA-induced increase in DNA per cent is related to polyoma virus induced cellular DNA synthesis¹¹. It is well known that cells of chemically induced tumours contain a mosaic of surface antigenic properties¹² acquired during transformation. The system described here in which the concentration of carcinogen can be limited in its reaction with single cells might prove useful in the induction and identification of intracellular antigens as well as a defined number of phenotypically expressed surface antigens.

RADIOBIOLOGY

Effect of Sodium Alginate in inhibiting Uptake of Radiostrontium by the Human Body

THE selective inhibition of radiostrontium uptake by rats following the administration of doses of sodium alginate has been reported recently¹⁻³. We have performed a similar experiment with a normal healthy adult human male volunteer, in order to see whether sodium alginate was effective in inhibiting uptake of radiostrontium from the human gastro-intestinal tract.

In the first stage of the experiment, 10 g sodium alginate was administered orally to the subject, during the morning, 20 min prior to an oral administration of 0.36 μ c. strontium-85 (0.51 MeV γ -rays; half-life, 65 days). No food had been consumed since the previous evening. Regular measurements of body radioactivity were made by means of the Windscale whole-body counter⁴ in order to determine the time pattern of retention of strontium-85 in the human body. All urine and faeces excreted during the 9 days following administration were collected and analysed for strontium-85 and calcium. When after 23 days the amount of strontium-85 retained in the body had dropped below the limit of detection (5 nc. strontium-85), the first stage of the experiment was completed.

The second stage involved the oral administration of 0.48 μ c. strontium-85 to the same subject, under conditions identical with those of the first stage, except that no sodium alginate was administered. Similar body radioactivity measurements of strontium-85 were again made and excreta collected and analysed for strontium-85 and calcium.

The γ -ray spectrum obtained from each measurement of body radioactivity was corrected for the subject's body content of the naturally occurring potassium-40 and fall-out calcium-137. The net counting rates in the strontium-85 photopeak, corrected for physical decay, are pre-

sented in Fig. 1 for each stage of the experiment. It can be seen (Fig. 1) that after day 5, the amount of strontium-85 retained in the body was lowered by a factor of approximately 8 when sodium alginate was administered.

The amount of strontium-85 excreted in urine was also lower in the first stage of the experiment (Fig. 2) than in the second stage, by a factor of approximately 10.4 averaged over the 7 days following administration.

In each stage of the experiment, one blood sample was taken from the subject at about 2.5 h after administration. Assessments were made of the amounts of strontium-85 and calcium in serum, and the results showed that the ratio of strontium-85 to calcium in serum in stage one of the experiment was lower by a factor of about 9.2 than that in the second stage.

Although the second stage of the experiment has not yet been completed, these preliminary results clearly show that sodium alginate has been effective in reducing

Fig. 1. Body retention of strontium. ----, Without sodium alginate; —, with sodium alginate

Fig. 2. Daily excretion of strontium in urine. ----, Without sodium alginate; —, with sodium alginate

- the amount of strontium-85 transferred from the human gastro-intestinal tract to blood and whole body (and presumably bone) by a factor in the range 8–10.4.

Sodium alginate is non-toxic at the level used in this experiment, and selectively inhibits the uptake of radiostrontium without significantly interfering with the uptake of calcium by the body^{1,2}. The ability to inhibit selectively the uptake of radiostrontium from the gastro-intestinal tract would seem to be of definite value in the event of contamination of food or water with radiostrontium. The effect of food in the stomach at the time of administration of sodium alginate, however, has not as yet been worked out. After an accidental inhalation of radiostrontium, quite a large proportion of material may be cleared from the respiratory tract to the gut; in this event there may also be a place for alginate therapy.

Our present programme of experiments is designed to assess the effect of sodium alginate administered before, with or after an intake of radiostrontium, and also to assess the optimum doses and type of sodium alginate. It is also proposed to see whether the degree of inhibition is affected by the contents of the stomach.

A low viscosity form of sodium alginate ('Manucol SS/LD', supplied by Alginate Industries, Ltd.) was used in this experiment.

BIOLOGY

Production of Carotenoid by a Green Alga

THE first observations on carotenoid production by the chlorophycean alga *Dictyococcus cinnabarinus* were made by Wenzinger¹, Haag² and recently Kol³. From experiments carried out on static culture and for periods of a few months of growth, these authors reported that when sugars were present in the medium the cultures changed colour from green to red. The production of redness, they observed, was due to the prevalence of carotenoids in the chlorophyll formed.

Starting from these observations we decided to investigate the behaviour of *Dictyococcus cinnabarinus* and the eventual carotenoid production in submerged culture using different sugars, with and without addition of carbon dioxide, and in different conditions of temperature and light.

The experiments were performed in 500-ml. Erlenmeyer flasks containing 100 ml. of culture broth, on a rotatory shaker duly thermostated and illuminated. Illumination was supplied by fluorescent tubes ('warm white' type) which gave a light intensity of 3,500–4,000 lux. The strain used was *Dictyococcus cinnabarinus* 280 ('Kol-F. Chodat') (obtained from the algal collection of the Botanical Institute of the University of Geneva) and as culture broth, Detmer medium, diluted three times, was used. In the experiments with addition of carbon dioxide, a mixture of

air containing 3 per cent carbon dioxide was supplied to each flask at a rate of 0.5 v/v medium/min.

Each experiment lasted about 2 weeks and the following sugars were tested: glucose, fructose, galactose, lactose and sucrose, at a concentration of 2 per cent w/v of the culture medium.

200,000 cells/ml. grown in a seed flask containing Detmer/3 medium without sugar were inoculated into the 'fermentation' flask. It must be emphasized that in the absence of sugars the culture remained green, while in the presence of sugars, namely glucose, the culture changed colour gradually from green to yellow, to pink up to an intense orange colour by the end of the fermentation, which indicated accumulation of carotenoids.

The experiments showed that in the presence of glucose a good growth is obtained with a sugar utilization of 40–50 per cent, while other sugars are not utilized and the growth is quite poor; that supply of carbon dioxide does not interfere with the utilization of carbohydrates. Furthermore, the results have shown that the optimum for inoculum is 200,000 cells/ml. of green culture, each cell having a diameter of 5 μ , and in the red culture 10–12 to 20–25 μ (the latter are aplanosporangia, that is, mother cells in sporogony); that the optimum temperature is 25°; and that the best growth is obtained when 12 h of light is alternated with 12 h of dark.

For pigment determination, the cells collected by centrifugation were ground in a mortar with Na₂CO₃ and 'Celite', adding gradually 80 per cent aqueous acetone; the acetone solution was then extracted with light petroleum. The absorption spectrum of the ethereal extract was determined between 400 and 700 m μ using a Cary spectrophotometer.

Thin-layer chromatography was used for the preliminary characterization of the pigments. Amounts sufficient for their identification were obtained by column chromatography on 'Florisil' or alumina. Elution was effected with a gradient of acetone in light petroleum (b.p. 40°–70°). Coloured fractions belonging to each band were pooled, evaporated and examined in the spectrophotometer.

Six fractions of colour ranging from yellow to red were separated and identified as follows:

- (1) β -Carotene (epiphasic), 5–6 per cent of the total; m μ 478,450 (425) in light petroleum, m μ 515,485 (458) in carbon disulphide—plates yellow or orange—yellow—m.p. 174°.
- (2) Echinenone (90 per cent epiphasic); m μ 456–458 in light petroleum, m μ 488 in carbon disulphide; by reduction with LiAlH₄ gives isocryptoxanthin.
- (3) Unidentified (epiphasic); m μ 462 in light petroleum, m μ 500 in carbon disulphide.
- (4) Unidentified (epiphasic); m μ 470 in light petroleum.
- (5) Xanthophyll (hypophasic); traces—m μ 471, 441, 420 in light petroleum.
- (6) Unidentified (hypophasic); traces.

The spectra of fractions I and II can be superimposed on those taken with pure samples.

It is interesting to emphasize finally that in the cultural conditions which we describe, no chlorophyll could be detected; echinenone does not seem to have been previously demonstrated in the Chlorophyceae.

A Functional Relationship between Neurosecretory Fibres and Pituicytes in the Eel

SYNAPTIC contacts between neurosecretory fibres and pituicytes have been demonstrated in the eel, and the suggestion made that this association might form part of a mechanism for feed-back of information to the hypothalamus¹. Recent experimental investigations support this view.

Fifty eels were kept in darkness for 3–5 weeks and then transferred to illuminated white or black backgrounds for 4 h. The pituitaries of the white background animals showed the following features in contrast to those of eels kept on a black background:

(1) Many synapses between neurosecretory fibres (with elementary neurosecretory vesicles of 1200 Å diameter) and pituicytes.

Fig. 1. An electron micrograph showing part of a group of pituicytes in the pituitary of an eel maintained on an illuminated white background. Membrane-bound secretory inclusions may be seen. C, Colloid

Fig. 2. A diagram depicting a possible feed-back mechanism linking the proximal and distal parts of the hypothalamic-hypophysial neurosecretory system of the eel. a, Preoptic nucleus (NPO); b, synapse; c, pituicyte; d, periodic acid-Schiff-positive colloid. III V, third ventricle of brain

(2) A great number of membrane-bound secretory droplets, about 4000 Å in diameter, in the pituicytes.

(3) Much periodic acid-Schiff-positive material in the central canals (Fig. 1), surrounded by pituicytes; these canals appear to be in communication with the ventricles of the brain.

All these features were rare in control animals and black background animals.

These observations are consistent with a view that in the eel neurosecretory fibres may stimulate pituicytes to release their products into the cerebrospinal fluid. By so doing they might affect the preoptic nuclei since it has been shown that dendrites of the perikarya of the neurosecretory neurones project into the ventricles of the brain in the eel², frog³ and toad⁴.

An association of neurosecretory fibres and ependymal cells has been demonstrated in a bird⁵, and recently it has been shown that ependymal cells in the median eminence of the rat appear to have a glandular function and secrete into the cerebrospinal fluid, though no synaptic contacts between these cells and nerve fibres were observed⁶.

The cerebrospinal fluid could act as a means of transport between the pituitary and the hypothalamic nuclei and thus provide a channel for the transfer of information from the distal to the proximal part of this neurosecretory system. The work recorded here suggests a possibility that pituicytes or other glial elements might play an important part in such a process.

A Dual Neurosecretory Innervation of the Pars Distalis of the Pituitary of the Eel

INVESTIGATIONS of the innervation of the eel pituitary with the light microscope demonstrated in the pars distalis a few nerve fibres which stained with the Gomori technique and many others which did not¹. The latter, which appeared to originate in the nucleus lateralis tuberis, do not seem to stain with any of the common 'neurosecretory' stains², and therefore under the light microscope the degree of neurosecretory control of the pars distalis appears to be slight.

Under the electron microscope, however, an extensive neurosecretory innervation of the pars distalis can be demonstrated. Most of the fibres which invade the anterior lobes of the pituitary (proximal and rostral pars distalis) are seen to contain vesicles, irregular in outline, each with a central electron-dense granule about 700 Å in diameter. These fibres are found also, with their perikarya, in the nucleus lateralis tuberis; they resemble the Type B neurosecretory fibres described in the neuro-intermediate lobe of the elasmobranch pituitary³. They do not stain with neurosecretory stains, but nevertheless should be termed neurosecretory⁴; they discharge into perivascular and intervascular spaces which permeate the pars distalis.

Material with affinity for neurosecretory stains appears in abundance only in mature eels in which there is evidence of an increased activity of GTH and TSH cells⁵. In these animals many typical neurosecretory fibres containing Type A elementary neurosecretory vesicles⁶, about 1400 Å in diameter, are found. These fibres were extremely rare in elvers or young eels.

Fig. 1. Electron micrograph of a portion of the rostral pars distalis of an eel pituitary, showing a neurosecretory fibre tract lying between groups of ACTH cells. B, Type B fibre containing electron-dense granules, each about 700 Å in diameter.

There is evidence, therefore, at the level of ultra-structure for a neurosecretory innervation of the pars distalis of the eel by at least two kinds of neurosecretory fibre, and that the activity of one fibre type (Type A) may be correlated to stages of the life-cycle.

Control of Furunculosis in Impounded Adult Salmon

FROM July 27 to August 17, 1964, 17 salmon were found dead among about 40 fish impounded at Ceannacroc on the Moriston, a tributary of the River Ness. Eight salmon examined between August 1 and 14 showed typical symptoms of furunculosis, and pure cultures of the causative organism, *Bacterium salmonicida*, were isolated from the internal organs and muscle. As a serious outbreak of furunculosis had occurred in this impoundment and at another impoundment on the Ness system in 1963, an attempt was made to control the outbreak which seemed to threaten this year.

It was decided to use an intramuscular depot injection, so as to maintain the highest blood levels of antibiotic for the longest time after a single injection. Chloramphenicol was chosen as the antibiotic since it is known to be effective against *B. salmonicida* both *in vitro* and *in vivo*¹. Chloramphenicol has a low solubility in water so that an aqueous suspension would provide a depot in the muscle which would be dissipated slowly. 'Intramycin', a veterinary preparation containing 15 per cent chloramphenicol in aqueous suspension (Parke Davis and Co.), was used at a rate of 1 ml./15 lb. of fish. At this rate, a single intramuscular injection of this preparation should supply effective blood levels of chloramphenicol for 24–48 h.

All the impounded fish were treated on August 17. The fish were injected on the left side slightly anterior to the dorsal fin and towards the heart and coelom, the

needle being inserted to its full extent. Sterile disposable plastic syringes were used, with needles 21 gauge, 1.5 in. long. A total of 44 fish was treated, including seven fish which were being transferred to the impoundment from the trap nearby.

Two fish died within a few hours after the injection. These were in a decidedly poor condition before treatment, and handling and injection may have hastened their death. Two more fish died later, one on September 6 and one on October 9. Unfortunately it was not possible to examine any of these fish after death. Following the treatment given on August 17, ten more fish were added to the impoundment from the trap. All these were injected before being placed in the impoundment and they, and the other fish impounded, have apparently remained healthy and normal.

It should be emphasized that this treatment was devised to meet an emergency, but the results obtained suggest that a rigid experimental investigation would confirm the results of this *ad hoc* test. If this should be so, the treatment has a number of advantages: it is easily carried out and can readily be taught to non-technical staff; it seems to have no adverse effect on the fish; and it is inexpensive, as it is estimated that 50 fish could be treated for less than £5.

I thank Mr. J. Wood, superintendent to the Ness District Fishery Board, and his staff, for their help.

Action of Gibberellic Acid on Auxin Transport

THE polar transport of β -indolylacetic acid (IAA) in plant organs has been known since the observations of Went¹ and van der Weij². Most of the direct investigations of IAA movement have used bioassays for detecting auxin³. But these analyses have been limited by the sensitivity of the method⁴. The recent use of IAA labelled with carbon-14 (IAA*) facilitates the study of the auxin translocation⁵.

It has been previously observed that, in the stem sections of *Lens culinaris*, there is a predominantly basipetal movement of carbon-14 from applied IAA*. It has been assumed that gibberellic acid (GA) increases the uptake of IAA* and changes the auxin transport in these sections⁶. In the present communication, the action of GA on the velocity of IAA* translocated in the section of the stem of *Lens culinaris* Med. will be discussed.

The movement of IAA* (¹⁴C-labelled in the carboxyl group: specific activity of 8 mc./mmole) has been examined in 6-mm sections, using the technique of McCready⁷ and Pilet⁸. The agar (1.5 per cent) blocks were 16.6 mm³ in volume. The donors contained 5 or 50 μ moles of IAA*. At the end of each experiment, each set of forty replicate blocks was pooled for the analysis of their radioactivity—these were expressed in counts per min (c.p.m.) per mg of dry weight.

Seeds were soaked for 4 h and then placed in Petri dishes on filter paper with de-ionized water for 24 h. Seedlings were then selected (4 mm roots) and planted under the same conditions⁹. After 72 h, when used for experimental purposes, the stems were 10 mm \pm 2 mm long. All experiments were carried out at 25.0° C, in complete darkness. During manipulation only green light was used.

The principles involved in the assay are shown diagrammatically in Fig. 1. After an incubation of 2 h in Ringer's solution containing (or not) GA, the sections (40 for 25 ml.)

Table 1. EFFECT OF A PRETREATMENT ON THE TRANSLOCATION OF ^{14}C FROM IAA*

are placed, for 6 h, in the horizontal position. Table 1 shows the results of a typical experiment using, as a control, sections without pretreatment in Ringer's solution. It can be observed: (a) The Ringer's solution reduced the uptake of carbon-14 from IAA*. (b) For

Fig. 1. Diagram showing the principles of the method used to study the action of gibberellic acid on the transport of carbon-14 from IAA* in the donor blocks. S, Section of the stem; apical (A) and basal (B) cut surfaces; donor (D) and receiver (R) blocks; NP, not pretreated; P, pretreated

the GA-pretreatment the radioactivity in the sections was much reduced. (c) These effects increased when the GA concentration was increased.

The velocity of carbon-14 translocation was estimated in the manner introduced by van der Weij, incorporating later improvements by Jacobs¹⁰ and McCready and Jacobs¹¹. The method involves plotting the amount of IAA* translocated through the sections (length: L) against time. The presumed line is then extrapolated back to 'zero IAA*', and the time-intercept so determined is taken as the time (T) required for auxin to be transported in the section. Assuming (Pilet⁶) that the regression is:

$$y = mx + h$$

(y , radioactivity in receivers; x , diffusion time), the velocity (V) of movement can be calculated from:

$$V = L/T \text{ and } T = -h/m$$

The time course of transport of carbon-14 with IAA* in donors was first analysed (Fig. 2). For each experiment, the net increase of radioactivity in the receivers follows an apparently linear course over the period 1–6 h. The calculated intercepts are given in Table 2. From these results it can be concluded that: (a) The velocities for 5 and $50\ \mu\text{M}$, respectively, are not significantly different from each other according to statistical tests. (b) The mean calculated velocity is, for the control (A, C, E), 5.69 mm/h and, for the treated sections (B, D) with GA ($50\ \mu\text{g}/\text{ml}$), 9.83 mm/h.

Table 2. CALCULATION OF THE VELOCITY OF TRANSPORT OF ^{14}C FROM IAA* (see Fig. 2)

Donor blocks, IAA* (specific activity, 8 mc./mmole; standard (D_0), $5\ \mu\text{M}$ $1,160 \pm 27$ c.p.m. and $50\ \mu\text{M}$ $11,080 \pm 160$ c.p.m.); diffusion time, 2–6 h; pretreatment (see Table 1); concentration of GA, $50\ \mu\text{g}/\text{ml}$.

Assays	Length	Regression equation $y =$	T (h)	V (mm/h)
Initial concentration				
5 μM				
No pretreatment (NP) A	6.30	$(20.6) \cdot x - (24.3)$	1.18	5.34
Pretreatment (P)				
Ringer + GA B	6.48	$(30.9) \cdot x - (19.8)$	0.64	10.05
Initial concentration				
50 μM				
No pretreatment (NP) C	6.42	$(80.7) \cdot x - (80.1)$	0.99	6.48
Pretreatment (P)				
Ringer's E	6.50	$(63.7) \cdot x - (79.0)$	1.24	5.24
Ringer's + GA D	6.24	$(105.2) \cdot x - (68.4)$	0.65	9.60

$y = mx + h$. $T = -h/m$. $V = L/T = L/(-h/m)$. L , Length of sections. T , Time required for carbon-14 to be transported through the section.

Consequently, gibberellic acid causes an increase of both uptake and movement (velocity) of auxin applied, in donor blocks, on the cut apical surface of the sections of *Lens* stem.

Growth Responses of Mature Endosperm in Cultures

THE endosperm is usually a triploid tissue which supports the growth and germination of the embryo, and stores reserve food materials in mature seeds.

The immature endosperm of several plants undergoes proliferation on synthetic media, but only in two plants—*Santalum album*¹ and *Ricinus communis*²—has the mature endosperm yielded a continuously growing undiffer-

Fig. 2. The early stages of the time course of transport of carbon-14 from IAA* supplied at an initial concentration of $5\ \mu\text{M}$ (---) and $50\ \mu\text{M}$ (—) in the donors. Fig. 1. *Exocarpus cupressiformis*. A, Entire endosperm with intact embryo; stage of inoculation ($\times c. 2.8$); B, 11-week-old culture on BM+IAA (1 p.p.m.)+K (1 p.p.m.)+CH (400 p.p.m.) showing surface callusing of endosperm ($\times c. 2.2$); C, 5-week-old culture on same medium; note differentiation of shoot buds on the endosperm and germination of embryo ($\times c. 2.5$); D, E, sections of endosperm shown in C; note the unaffected embryo in D and differentiation of shoot buds in D and E ($\times c. 10$). c, Callus; em, embryo; end, endosperm; h, hypocotyl; r, root; s, shoot

entiated tissue. Both these are under investigation in this laboratory.

We have recently obtained a differentiation of shoots in cultures of the mature endosperm of *Exocarpus cupressiformis*, a member of the Santalaceae. The mature entire endosperm with intact embryo (Fig. 1A) was surface-sterilized with chlorine water for about 15 min, repeatedly washed with sterile water, and inoculated on a semi-solid modified White's medium containing 2 per cent sucrose (BM). IAA; 2,4-D; CH (casein hydrolysate); K (kinetin) and YE (yeast extract) were used as supplements. The cultures were maintained at $25^{\circ} \pm 2^{\circ} \text{C}$ and 50–60 per cent relative humidity under diffuse light.

There was no response on BM+CH (500 p.p.m.). If the concentration of CH was increased to 1,000 p.p.m., 20 per cent of the cultures showed germination of the embryo. However, on BM+IAA (1 p.p.m.)+K (1 p.p.m.)+CH (400 p.p.m.), after three weeks, surface callusing of endosperm occurred in 29 per cent cultures (Fig. 1B) and germination in 25 per cent (Fig. 1C). Occasionally, the same cultures showed both these features, and in some of them shoot buds also differentiated from the endosperm (Fig. 1C).

Figs. 1D and E represent microtome sections of the endosperm shown in 1C. It may be noted that in Fig. 1D the embryo is completely unaffected and shoot buds have developed superficially from the endosperm itself (Fig. 1E). They have a well-differentiated vascular supply and several foliar primordia which were chlorophyllous. In between the shoot buds, the peripheral region of endosperm shows distinct patches of vascular tissue. Some of the shoot buds appeared on the lower side and were embedded in the medium; others developed on the upper side and had no direct contact with the medium.

We have also cultured the endosperm of another member of the Santalaceae, *Osyris wightiana* (Fig. 2A). There was some callusing of the endosperm (Fig. 2B) in 20-week old cultures on BM+2,4-D (5 p.p.m.)+CH (1,000 p.p.m.). If the concentration of CH was reduced to 500 p.p.m., callusing was much more profuse (Fig. 2C). Squashes of callus showed cells of various sizes and shapes, and patches of tracheidal cells. When BM was supplemented with IAA (2 p.p.m.) and K (5 p.p.m.), instead of callusing the endosperm produced superficial outgrowths which showed distinct patches of vascular tissue (Figs.

Fig. 2. *Osyris wightiana*. A, Entire endosperm with intact embryo; stage of inoculation ($\times c. 2.1$); B, surface callusing of endosperm on BM + 2,4-D (5 p.p.m.)+CH (1,000 p.p.m.) in 20-week-old culture ($\times c. 1.8$); C, 22-week-old culture on BM+2,4-D (5 p.p.m.)+CH (500 p.p.m.) showing profuse proliferation of endosperm ($\times c. 1.5$); D, 12-week-old culture on BM+IAA (2 p.p.m.)+K (5 p.p.m.); note development of outgrowths with well-differentiated vascular tissue ($\times c. 9$); E, enlarged view of one outgrowth ($\times c. 72$). c, Callus; end, endosperm; og, outgrowth; v, vascular bundle

2D and E). Germination of the embryo occurred in 75 per cent cultures. In contrast to *E. cupressiformis*, the vascular tissue did not develop on the periphery of the endosperm proper.

Fig. 3. A, B, *Putranjiva roxburghii*; C, D, *Jatropha pandurafolia*. A, C, Entire endosperm with intact embryo; stage of inoculation ($\times c. 3.5$); B, D, 7-week-old (B) and 13-week-old (D) cultures on BM+2,4-D (2 p.p.m.)+K (5 p.p.m.)+YE (2,500 p.p.m.) showing proliferation of endosperm (B $\times c. 2.5$; D $\times c. 1.5$)

Results of endosperm culture of two members of the Euphorbiaceae—*Putranjiva roxburghii* and *Jatropha pandurafolia*—may also be mentioned. The stage of inoculation is shown in Figs. 3A and C. There was excessive proliferation (Figs. 3B and D) of endosperm in 7- to 13-week-old cultures on BM+2,4-D (2 p.p.m.)+K (5 p.p.m.)+YE (2,500 p.p.m.). The callus consists of cells of variable shapes and sizes, and differentiation of vascular tissue is quite common. In this or in any other treatment none of the cultures has so far shown any differentiation of shoot buds as in *E. cupressiformis*, or vascularized outgrowths as in *O. wightiana*.

There is no previous report of the *in vitro* differentiation of endosperm into roots and shoots. In *E. cupressiformis* the shoots clearly differentiate from the endosperm. The work is being further extended to obtain fully differentiated plants from this and other endosperms.

We thank Prof. P. Maheshwari for his advice; Prof. G. L. Davis (Armidale, Australia) for providing fresh fruits of *Exocarpus cupressiformis*; and Prof. R. D. Adatia (Bombay) and Dr. S. P. Kapoor (Poona) for providing fresh fruits of *Osyris wightiana*.

Ascent of Sap in Trees: Effect of Negative Absolute Pressure on Flow Resistance

IN considering the ascent of sap in trees, it is generally accepted¹ that the transpiration process at the leaves somehow 'pulls' the sap up through the xylem vessels in the tree trunk during active transpiration periods. This 'cohesion theory' postulates that negative absolute pressure (liquid tension) must be present in trees more than 34 ft. high, or in any plant where the combined effects of hydrostatic head and flow resistance produce a pressure drop of more than one atmosphere. Investigators have had little success, however, in applying traditional resistance laws to the calculation of viscous pressure drop. Theoretical estimates of flow resistance to sap movement have varied by several orders of magnitude² and experimental checks of flow resistance through sections of trees frequently show the flow rate decreasing with time at constant pressure³. It appears that the present resistance 'law' is incorrect, is being misinterpreted, or the viscosity of sap is not what it is assumed

to be from measurements made at positive pressures. This communication is relevant to the latter possibility and reports, in particular, on whether negative absolute pressures have any detectable effect on flow resistance.

Although water is used as the primary viscosity standard for Newtonian liquids⁴, several reports of anomalous behaviour can be found in the literature⁵. Also, since 1945, the investigations of flow resistance from a continuum mechanics point of view have shown that many fluids exhibit anomalous behaviour when subjected to special flow conditions. Truesdell⁶ discusses this possibility in defining a dimensionless parameter called the 'truncation number' for a 'Stokesian fluid' which is a simple generalization of the Newtonian fluid. He suggests that the classical linear theories become inadequate if the truncation number approaches unity, that is, the ratio of the viscosity times deformation rate divided by the pressure is of order of magnitude one or greater. As an example of the possible non-linear behaviour, Truesdell cites the deformation rate required for water.

Since this truncation number goes to infinity when the pressure is reduced to zero absolute, it was postulated that the flow resistance might be affected and have some bearing on the ascent of sap in trees. Further motivation for the experiment arose from the absence of data in the literature on viscosity measurements at negative absolute pressures.

In order to measure the flow resistance of water and a sap-like substance (an aqueous solution of corn syrup), a falling-head viscometer was constructed which placed the test liquid in tension by hanging dual columns of mercury from the liquid in the capillary viscometer (Fig. 1). The absolute pressure was varied from plus one atmosphere absolute to minus one atmosphere absolute by varying the height of the mercury in the barometer column relative to the height of the mercury-test liquid interface in the tension column. Viscometric measurements were made by displacing the interface from its equilibrium position and measuring the time required for the displaced interface to fall a given distance as determined by a cathetometer⁷.

Operation of the falling-head viscometer was as follows: With the entire system evacuated to 10^{-3} mm mercury, degassed water at 95° C was admitted to the capillary tube, tension columns, and main reservoirs through the Kern stopcocks. More hot water was flushed through the system to remove any remaining gas pockets. The valves were closed, and the system pressurized to two atmospheres by raising the mercury reservoirs. After allowing several days for the smallest bubbles to go into solution, water was removed through the Kern stop-

cocks, allowing the mercury to rise to near the top of the tension column. The absolute pressure of the water in the capillary was reduced to zero absolute or less by lowering the mercury reservoirs and observing the level of the mercury in the barometer columns relative to that in the tension columns. The viscometer was operated by closing the cross-connexions and raising one reservoir slightly to displace the mercury interface from its equilibrium position. The cross-connexion was opened, and the time required for the displaced interface to fall a predetermined distance was measured.

The results of the experiments on degassed, distilled water indicate that the viscosity of distilled water remains essentially unchanged in the range of pressures from plus one to minus one atmosphere absolute. All observed values of viscosity were well within 1 per cent of the arithmetic mean value. Since the experimental uncertainty was estimated to be about 1 per cent, it was concluded that any change in viscosity with pressure could not be detected with this apparatus. The same result was obtained for aqueous solution of Karo syrup up to five times as viscous as water, so it would appear that negative absolute pressure has no detectable effect on the resistance to sap movement in trees.

The results of the tests at pressures near zero absolute indicate that the previously mentioned 'truncation number' is not a similarity parameter for the flow of water. Since no non-linear effects were observed, even with a truncation number of infinity, it appears that the past use of water as an example of a Stokesian fluid with zero natural time is questionable since the purpose of such an example was to show how certain abnormal conditions might result in non-linear effects. In a forthcoming article⁸, Truesdell considers only gases in his discussion of the Stokesian fluid. He also eliminates the pressure from the denominator of the truncation number by using the perfect gas law. This removes the possibility of an infinite truncation number for any condition involving actual materials which are assumed to be continuous media.

Pressures below minus one atmosphere absolute could not be attained with the apparatus used because of nucleation problems at the mercury interface. The pressures achieved are comparable with those attained by others using the mercury column technique⁹, but do not approach the tensile strength of 280 atmospheres recorded using a centrifuge¹⁰. Contrary to the nucleation criteria set up by Weyl and Marboe¹¹, a solid surface does not seem to be required for nucleation. In this experiment, nucleation always occurred at the test fluid-mercury interface. Since mercury has an atomic structure quite different from water (they share no hydrogen bonds as water and glass do), this type of structural discontinuity is evidently sufficient to provide nucleation sites at the interface.

Unique to this experiment was the use of the O-ring glass joints and hydrophilic stopcocks (glass stem and

rubber diaphragm) in contact with the water under tension. When nucleation occurred at the mercury interface, the stopcocks were used to remove the resulting gas bubble. Nucleation was never observed to occur in the joints or in the stopcocks. Parts of this type should be useful in future attempts to measure negative absolute pressure in living trees.

The apparatus also made possible approximate estimates of the bulk modulus of water and it was found that degassed water at pressures near zero absolute has about a 100 per cent increase in isothermal compressibility over the commonly quoted value for 15 atmospheres. This trend agrees with the variation in bulk modulus for pressures between 1 and 15 atmospheres reported by Kerr¹².

Respiratory Changes in the Cacao Seed Cotyledon coincident with Seed Death

CACAO seed sensitivity to cold was first demonstrated by Boroughs and Hunter¹. Previous investigations by Ibáñez^{2,3} have shown that a treatment of 4° C for 10 min will destroy viability in these seeds. Such a viability loss, however, was reversible if the seeds thus chilled were immersed for 10 min in a water bath at 37° C. Under such conditions, at least 85 per cent of the seeds remained viable and grew into healthy plants. After 15 min of such a cold treatment, however, no amount of post heat treatment could prevent ultimate death of the seed.

Subsequent work by Ibáñez⁴ has shown that the area of the seed most affected by the cold was the cotyledon and not the white embryonic tissue. Respiration rates in radicular tissue remained unchanged regardless of temperature treatment, while cotyledonary tissue showed a large increase in endogenous respiration after cold treatment. In addition, chilled embryonic tissue, growing in a sterile medium, independent of cotyledon material, developed into a small plant, as did normally treated material.

In this investigation we have attempted to relate the onset of cold-death irreversibility in the cacao seed with increases in endogenous respiration in the cotyledonary tissue following cold treatment.

Seeds of *Theobroma cacao*, clone UF-613, were taken from mature pods and submitted to the following treatments:

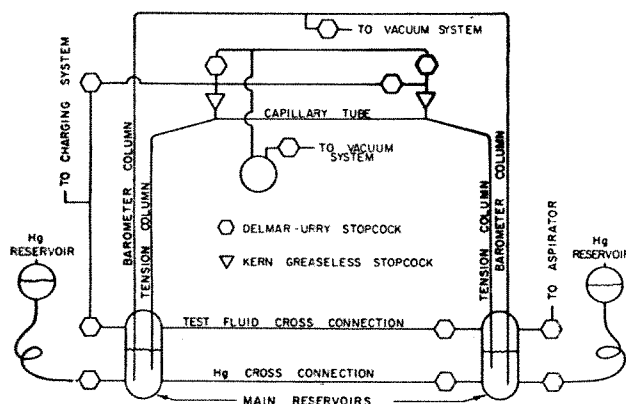

Fig. 1. Falling-head viscometer

Fig. 1. Respiration in cacao cotyledon tissue following various cold treatments. Δ , Normal; \circ , 5 min at 4°C ; \square , 10 min at 4°C ; \blacktriangle , 15 min at 4°C ; \bullet , 20 min at 4°C ; \blacksquare , boiled control.

Fig. 2. Respiration in chilled cacao cotyledon following incubation at 37°C . Δ , Normal; \circ , 5 min at 4°C ; \square , 10 min at 4°C ; \blacktriangle , 15 min at 4°C ; \bullet , 20 min at 4°C ; \blacksquare , boiled control.

Normal control seeds were immersed in water at room temperature (25°C) for 5, 10, 15 and 20 min. Seeds subjected to cold treatment were immersed in water at 4°C for periods equal to those given here for the normal control. In addition, a group of cold-treated seeds received post heat treatment in water at 37°C for periods equal to the individual treatment periods given here.

The exposure times were chosen because of previous work³, which showed that a treatment of 5 min at 4°C had an appreciable killing effect on seed viability while a 10-min treatment was almost 100 per cent effective in killing the seed. These processes, however, were reversible by post heat treatment at 37°C . A treatment of 15 min at 4°C killed the seed and post treatment at 37°C did not reverse this effect. The chilling process was carried further in the 20-min treatment.

After cold treatment, the radicular tissue was removed from the seeds and the cotyledonary material was cut with a cork borer of small diameter to yield pieces of approximately 200 mg in weight. These samples were then added to Warburg flasks containing the following ingredients: 0.1 ml. potassium phosphate buffer pH 7.0, 0.1 M; 200 mg cotyledonary material; 0.2 ml. 10 per cent KOH (in the centre well); water to a final volume of 3 ml. The final

pH of the reaction was 7.0. The endogenous respiration reactions were measured at 30°C . The assay method used has already been described².

Fig. 1 demonstrates the respiration of the cotyledonary material after the various cold treatments and under normal conditions. These results represent the averages of five individual experiments. While there is some difference in respiration between normal tissue and tissue chilled for 5 min, and there is an appreciable increase in respiration of tissues chilled for 10, 15 and 20 min, over the respiration of the normal system, a boiled control showed no activity.

Fig. 2 outlines respiration in cotyledonary tissue after the various cold treatments, and post treatments at 37°C . Normal and 5 min at 4°C are practically indistinguishable from one another, while 10, 15 and 20 min at 4°C show an appreciable increase in respiration over the normal system. A boiled control showed no activity.

It is apparent that there is some relationship between the increase of respiration following chilling of cotyledonary material and the irreversible death point of the seed after cold treatment. This is supported by the fact that restoration of viability by post heat treatment results in a decrease in respiration of the seeds which have been chilled in water for 5 min at 4°C . This lower rate of respiration is practically indistinguishable from that of the normal system. However, the respiration of the seed following chilling in water at 4°C for 10 min remained at a relatively high level after post heat treatment, even though such treatment results in a restoration of viability of the seed. This indicates that increase in respiration in cotyledonary material has some relation to seed death, but it is a manifestation of processes occurring in the cell due to cold and not a direct factor in seed death.

Previous work with cacao seed^{3,4} has indicated that the major effect of irreversible cold-induced death occurs in the cotyledonary tissue during the period of 10–15 min in water at 4°C . The increase of respiration with chilling time suggests a progressive effect of cold treatment on the cotyledon. Such an effect could be attributed to a gradual change in the physiological properties of the cotyledon, possibly a solid-state change of membrane lipids. Restoration of viability following heat treatment could then be due, at least in part, to a reversal of such physiological change. While these data suggest that membrane damage in cotyledonary tissue is a direct result of cold treatment, how the process could occur is, as yet, unknown.

This investigation was supported by the U.S. Atomic Energy Commission under contract AT(30-1)-2043.

VIROLOGY

Mixed Infection of African Green Monkey Kidney Cells by Adenovirus 7 and SV 40

It has been shown that mixed infection with adenovirus 12 and SV 40 can occur in African green monkey kidney cells (AGMK)¹; moreover, the double infection results in an enhancement of adenovirus growth². In both the foregoing investigations it was demonstrated with electron microscopy that less than 1 per cent of the cells contained adenovirus 12 particles 72 h after infection with adenovirus alone, yet with adenovirus plus SV 40, 75 per cent of the cells contained adenovirus. Determinations of adenovirus infectivity in human embryonic kidney cell cultures using limiting dilution titrations also consistently demonstrated enhancement of adenovirus growth by SV 40. Similar results were obtained with adenovirus 5 by infectivity titrations and electron microscopy.

To investigate further this phenomenon, we measured haemagglutinin production as another parameter of adenovirus growth. Adenovirus 7 was chosen because of its capacity to agglutinate rhesus monkey erythrocytes. The prototype strain of adenovirus 7 was obtained from Dr. J. Kasel (National Institute of Allergy and Infectious Diseases, National Institutes of Health). It was serially passed in HEP-2 cells and titrated in primary human embryo kidney cells³. Primary AGMK tube cultures were inoculated with adenovirus 7 only and with adenovirus 7 plus SV 40 simultaneously using methods previously described^{1,2}. The tubes were incubated at 37°C on a roller drum for 72 h, frozen and thawed three times, and titrated. Haemagglutinin titres for rhesus monkey erythrocytes were determined using a micro-titre method³. To two-fold serial dilutions of 0.025 ml. tissue culture fluid, were added 0.025 ml. saline and 0.025 ml. 1 per cent erythrocytes in each micro-titre well. The titre plates were incubated for 1 h at 37°C and the end-point was read as the last dilution (of the original two-fold) in which a definite agglutination pattern was obtained. All experiments were performed in duplicate, and haemagglutination observations of each tube also were performed in duplicate. The quadruplicate haemagglutination results were the same for all titrations in this investigation. Infectivity titrations were carried out in roller tube cultures of primary human embryo kidney cells. Identical cultures with single and double infection were fixed, sectioned and examined with the electron microscope¹. The results are summarized in Table 1.

Table 1. INFECTION OF AFRICAN GREEN MONKEY KIDNEY CELL CULTURES WITH ADENOVIRUS 7 ONLY AND ADENOVIRUS 7 PLUS SV 40

Inoculum	Haemagglutinin titre*	Cells with adenovirus particles by electron microscopy*	Infectivity titre*
Adenovirus 7 (10 ^{5.2} TCID ₅₀)	0	0	10 ^{6.2} TCID ₅₀ /ml.
Adenovirus 7 (10 ^{5.2} TCID ₅₀) plus SV 40 (10 ^{6.4} TCID ₅₀)	1:32	20 per cent	10 ^{7.9} TCID ₅₀ /ml.

* 72 h after inoculation.

Although approximately 20 per cent of the cells examined electron-microscopically had intranuclear adenovirus particles, in a few cells there was morphological evidence of mixed infection with SV 40 particles and adenovirus particles within the same nucleus. The close association of the two viruses provides a morphological basis for the serological evidence of 'hybridization' of adenovirus 7 and SV 40 presented by Huebner *et al.*⁴.

Our findings show that the development of adenovirus haemagglutinin as well as mature infectious virus particles is enhanced by mixed infection with SV 40. This is consistent with the work of Brandon and his associates⁵, who report good evidence that haemagglutinin is an intrinsic part of the infective particle. In their experiments adenovirus 3 was adsorbed and eluted on monkey erythro-

cytes through three cycles, and more than 90 per cent of the infective particles accompanied the haemagglutinin. Thus, our investigation has provided additional affirmative evidence that adenovirus growth is enhanced by SV 40. Moreover, the quantitative haemagglutination technique is much less cumbersome for determining this phenomenon than infectivity titrations or electron microscopy.

CYTOLOGY

Isolation of Macronuclei from the Ciliate *Tetrahymena pyriformis* GL

SEVERAL different non-ionic detergents have recently been used for the isolation of nuclei from mammalian cells¹⁻⁵. One of these detergents, 'Triton X-100', was found to solubilize readily cytoplasmic components, without affecting the structural integrity (at the light-microscope level) of nuclei from rat liver cells and mouse plasma cell tumours⁵. 'Triton'-isolated nuclei contained more than 90 per cent of the DNA in the original cell homogenate, retained rapidly labelled RNA and NAD-pyrophosphorylase activity⁵. The detergent digitonin has been used with some success for the isolation of macronuclei from stationary phase *Tetrahymena pyriformis*, mating type II, var. 1 (ref. 6).

This communication describes a simple method for the isolation of macronuclei from the ciliate *Tetrahymena* after cell lysis in 'Triton X-100'.

Growth conditions for *T. pyriformis* GL and the method for collecting cells were the same as reported earlier⁷. Macronuclei were isolated from organisms in the following growth stages: (1) exponential multiplication at the optimum temperature for growth (29°C); (2) exponential cultures incubated for 2 h at 34°C; and (3) maximum stationary phase. Brief periods of incubation at 34°C were also used to induce synchronized cell division^{8,9}.

The gathered organisms were washed once at room temperature in a diluted Ringer's sodium phosphate (RSP) buffer (final concentration: 0.047 M sodium chloride, 0.002 M potassium chloride, 0.001 M magnesium sulphate, 0.0125 M sodium phosphate buffer, pH 7.3) and resuspended in the RSP-buffer to give a final density not exceeding 4×10^6 cells/ml. The suspension was gently shaken to avoid cell aggregation. From this suspension, 100 ml. was removed with a plastic pipette in 10-ml. portions and slowly added to 100 ml. of medium A (0.5 per cent v/v 'Triton X-100' and 0.5 M sucrose in RSP) in a 500-ml. Erlenmeyer flask kept in crushed ice. An L-shaped glass rod (2 × 27 cm, area of blade approximately 15 mm²) rotating at 200 r.p.m. in medium A was used for mixing. Five min after addition of the last aliquot of the cell suspension to medium A, almost all cells were completely lysed. From this time on, 200 ml. of medium B (2 per cent w/v proteose peptone, Difco, and 0.1 per cent w/v liver fraction L, Wilson Laboratories, in distilled water) were slowly added to the mixture while stirring continued.

Frequent examination of samples under a phase-contrast microscope showed that lysis in medium A started at the anterior part of the cell and swept along the long

axis to the posterior part, releasing cytoplasmic particles and the macronuclei. Medium B, a part of the growth medium of *Tetrahymena*, was found to stabilize the nuclei and to prevent their clumping and attachment to cytoplasmic fragments. More than 95 per cent of the nuclei were observed intact and their surface was found free from cytoplasmic contamination (by phase contrast microscopy). Such successful lysis could be obtained only with stationary-phase and heat treated cells. Less than 50 per cent of log-phase cells could be lysed by this method.

The lysed cell suspension was slowly passed through a cotton filter at room temperature, but collected in an ice bath. The filter was prepared by taking sterilized absorbent cotton (4-oz. packages, Parke, Davis and Co.), covering it on both sides with cheese cloth and cutting 6 x 6 in. squares, which were put into the bottom part of a polyethylene Buchner funnel (diam. 11 cm). The filtrate was then layered in 40-ml. portions on top of the following two layers in a 90-ml. round bottom, plastic centrifuge tube: bottom, 10 ml. of 1 M sucrose in RSP; intermediate layer, 30 ml. 2 per cent (v/v) 'Triton X-100' and 0.5 M sucrose in RSP. Centrifugation (PR-2 International Centrifuge, head No. 240) was carried out in three 5-min steps at 70, 250 and 800g. Deceleration was manually controlled to avoid mixing of the three layers. Mitochondria and small cell particles remained in the upper layer, inorganic particles (resistant to digestion in 1 N acid or alkali at 25° C) were found in the middle layer, while most nuclei formed a creamy membranous pellet at the bottom of the tube. The supernate was rapidly removed by suction, except 5 ml. covering the pellet. The remaining fluid was poured out gently and 1 ml. 1 M sucrose was then added to the pellet and repeatedly sucked back gently into a plastic pipette until the material of the pellet was in homogeneous suspension. This suspension was used for phase contrast microscopy and further purification in the following way. An equal amount of 2 M sucrose in RSP buffer was added to the suspension, carefully mixed, and a 2-ml. portion was layered over 2 ml. of 1.75 M sucrose RSP buffer in a 5-ml. cellulose tube and centrifuged for 20 min at 10,000 r.p.m. in an SW-rotor of the Spinco ultracentrifuge (model L). After decantation of the supernate, 1 ml. of 0.5 M sucrose was added to the gelatinous pellet and the nuclei were resuspended by gently pipetting as already described.

Phase contrast photomicrographs of macronuclei prior to the final purification step are shown in Fig. 1A. This fraction was found to be contaminated with small particles (diam. about 5 μ). These particles are virtually all removed by ultracentrifugation during the last purification. Examination of the final nuclear fractions in the electron microscope also failed to reveal contamination by cytoplasmic structures (Fig. 1B). The structure of these nuclei appears to be identical to the ultrastructure described by Elliott *et al.*¹⁰ in whole cell preparations of

T. pyriformis, mating type I, variety 1. It is of interest to note that the nuclear membrane was found to be present in all preparations examined. Nuclei isolated with 'Triton X-100' from rat liver, however, had lost most of their outer membrane⁶.

A preliminary investigation of DNA isolated from *Tetrahymena* nuclei indicated it to be fibrous and a good primer in an RNA-polymerase assay¹¹.

The work is being continued to adapt the present method to the isolation of nuclei from *Tetrahymena* cells in the exponential growth phase.

This investigation was supported in part by grant RG 06461-05 from the National Institutes of Health, Bethesda, Maryland.

GENETICS

Aggressive Behaviour, Mental Sub-normality and the XYY Male

It is well known that 1 per cent of males in institutions for the mentally sub-normal are chromatin-positive and that the majority of these have an XXY sex chromosome constitution¹. In 1963 Forssman and Lambert² reported on a survey of the nuclear sex of 760 male patients in three Swedish institutions for criminal and 'hard-to-manage' males of sub-normal intelligence. They found 2 per cent to be chromatin positive, but the chromosome constitution of these patients was not reported. Casey (personal communication) surveyed 942 males in two comparable institutions in England, and found 2.2 per cent of them to be chromatin-positive. He also studied the chromosomes of these 21 chromatin-positive males and found 7 to have either an XXY sex chromosome constitution or to be mosaics in which the XXY cells formed the major cell line. This finding of a third of the chromatin-positive males to have an XXY cell line contrasted sharply with that of Maclean and his colleagues, who studied 2,607 ordinary mentally sub-normal males, and found only 2 of the 28 chromatin-positive patients to have an XXY constitution. This contrast led us to wonder whether an extra Y chromosome predisposes its carriers to unusually aggressive behaviour. We decided that if this were the case, then we might expect an increased frequency of XYY males among those of a violent nature. The purpose of this communication is to report our findings in a survey of mentally sub-normal male patients with dangerous, violent or criminal propensities in an institution where they are treated under conditions of special security.

In the course of routine physical and haematological examination a blood sample was obtained for chromosome studies. Of

Fig. 1. Macronuclei isolated from *Tetrahymena pyriformis* GL in the stationary phase of growth. A, Phase contrast photomicrograph (scale = 10 μ); B, electron-micrograph. After final purification, the nuclei were resuspended in 0.5 M sucrose Ringer's phosphate buffer and fixed with 6 per cent glutaraldehyde for 30 min. The nuclei were then washed once with phosphate buffer (0.1 M, pH 7.4), post fixed with 1 per cent osmium tetroxide for 30 min, washed three times with distilled water and stained with 2 per cent uranyl acetate for 60 min. After quick dehydration, the samples were embedded in epon resin and sectioned 750 Å thick. A Hitachi HU 11 A electron microscope was used (\times c. 4,000).

the total of 203 patients available, six declined to give a blood sample so that chromosome observations were made on the remaining 197. We found that twelve had a chromosome abnormality; seven had 47 chromosomes and an XYY sex chromosome constitution, one had 48 chromosomes and an XYY sex chromosome constitution, and one was an XY/XXY mosaic. The remaining three had structural abnormalities of the autosomes; one had 45 chromosomes and a translocation between two chromosomes in group 13-15, one had 46 chromosomes with a reciprocal translocation between an autosome number one and an autosome number 16, and one had an apparent deletion of part of the long arm of an autosome in group 21-22.

The most important finding in this group is that eight individuals have an additional Y chromosome. Very little is known about the XYY male, as only a few cases have so far been described, and these refer to a heterogeneous group of children and adults from whose description no clear picture of the XYY male has emerged³⁻⁷. However, the finding that 3.5 per cent of the population we studied were XYY males must represent a marked increase in frequency by comparison with the frequency of such males at birth. On theoretical grounds XYY males at birth must be less common than XXY males, who form approximately 0.2 per cent of the new-born male population⁸. We have examined 266 randomly selected new-born male babies without finding an XYY individual, and we have also examined 209 randomly selected adult males, again without finding one with an XYY constitution. In addition, we have examined the chromosomes of approximately 1,500 males for a variety of reasons and only one of these was found to have an XYY sex chromosome constitution.

Further clinical investigations have yet to be undertaken on these abnormal patients, but it is already apparent that they are unusually tall. Among the 197 men we studied the difference between the mean height of the males with one Y chromosome (67.0 in.) and that of those with two Y chromosomes (73.1 in.) is highly significant ($P < 0.00001$). In fact in this particular group a man more than 72 in. in height has an approximately 1 in 2 chance of having an XYY constitution.

At present it is not clear whether the increased frequency of XYY males found in this institution is related to their aggressive behaviour or to their mental deficiency or to a combination of these factors. We are attempting to elucidate this problem.

We thank Dr. W. M. Court Brown for his help and encouragement, and Mr. Peter Smith for statistical advice.

PSYCHOLOGY

Tactile-vision: Thermal and Texture Cues in the Discrimination of Black and White

TEMPERATURE and texture have both been suggested as possible normal explanations of the 'skin-vision' phenomenon¹. Neither of them explains Russian claims of perception at a distance (claims not supported by Barrett and Rice-Evans² using a low level of illumination); however, they do provide potential cues in situations where touch is involved. Colourants may give surfaces with characteristic textures and the colour of a surface will affect the amount of heat it absorbs. Recently, Buckhout³ found that, even with illumination provided by a 40-W bulb (a good source of infra-red radiation), out of 80 subjects not one could distinguish between 10 colours in 90 presentations. He controlled texture by covering the colours with a thin layer of plastic. In the experiment reported here I investigated what part both texture and temperature might play in a very simple situation: that of a black-white discrimination.

The apparatus used was a 9 in. × 7 in. × 20 in. light-proof box comprising two compartments separated by a sheet of frosted glass. In one was a 60-W lamp and in the other a stack of 72 stimulus cards: 24 each of black, white, and half black and half white photographs of size 2.5 in. × 3.5 in. With one hand inside the box the subject went through the pack of cards, feeling each in turn and then guessing its type. After each guess he posted the card out through a chute in the side of the box, providing himself with knowledge of results. The subjects were given two sessions: one with the light on and one with it off. They were not aware of this difference and the order of the two conditions was alternated between them. The cards were shuffled in between sessions.

Fig. 1

Forty-eight students were tested. The mean number of correct guesses expected by chance is 24/72 for each condition. The observed means were 25.3 for light on and 24.2 for light off. Clearly texture was not used as a cue. Subtracting the dark from their corresponding light scores gave the results shown in Fig. 1. A Wilcoxon matched-pairs signed-ranks test gave a significance of $P = 0.014$, which can be seen to be due not to a few high scorers but rather to the group as a whole: discriminative ability being spread thin among the subjects. Under the hypothesis black and white is the easiest colour discrimination task, and yet subjects score only one or two correct guesses more than is expected by chance. It remains possible that with a lengthy series of trials this skill could be developed: subjects often reported holding a number of different hypotheses one after the other, and it might be that here they find difficulty in selecting the relevant aspects of their sensations.

FORTHCOMING EVENTS

Tuesday, December 28

INSTITUTE OF BIOLOGY (in the Lecture Hall of the Natural History Museum, Cromwell Road, London, S.W.7), at 3 p.m.—Dr. N. E. Hickin. "Being a Biologist" (Christmas Lecture for Children).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Sir Bernard Lovell, O.B.E., F.R.S., Prof. F. Graham Smith, Prof. Martin Ryle, F.R.S., and Dr. A. Hewish. "The Exploration of the Universe". (The One Hundred and Thirty-Sixth Course of Six Lectures Adapted to a Juvenile Auditory. Further Lectures on December 30, January 1, 4, 6 and 8.)

Wednesday, December 29

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 2.30 p.m.—Dr. J. K. S. Joseph. "Discovering Britain's Past from the Air" (Christmas Lecture for Children).

Monday, January 3

PLASTICS INSTITUTE (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 2.30 p.m.—Mr. J. E. Proctor. Young People's Lecture.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Sir Dudley Stamp, C.B.E. "Philatelic Cartography".

INSTITUTION OF MECHANICAL ENGINEERS, MEDICAL ENGINEERING WORKING PARTY (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Informal Discussion on "Human Co-ordination and Engineering Control".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. A. P. Prosser. "The Chemistry of Mineral Processing".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned

LECTURER IN THE DEPARTMENT OF PATHOLOGY—The Professor of Pathology, Department of Pathology, University of Edinburgh Medical School, Teviot Place, Edinburgh, 8 (December 31).

LECTURER or ASSISTANT LECTURER IN PURE MATHEMATICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (December 31).

LECTURER (with an Honours B.Sc. degree in biochemistry or equivalent qualification) in DENTAL BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (December 31).

PROFESSOR OF SOCIOLOGY at the University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 31).

SENIOR LECTURER IN MATHEMATICS; a LECTURER or ASSISTANT LECTURER IN MATHEMATICS; a LECTURER or ASSISTANT LECTURER IN STATISTICS, a LECTURER or ASSISTANT LECTURER IN OPERATIONAL RESEARCH, and a LECTURER or ASSISTANT LECTURER IN NUMERICAL ANALYSIS—The Registrar, Bradford Institute of Technology, Bradford, 7 (December 31).

ASSISTANT LECTURER IN SOCIAL PSYCHOLOGY—The Registrar, The University, Nottingham (January 3).

DIRECTOR (highly qualified scientifically with an aptitude for administration and negotiation with public bodies and others) OF THE NATURE CONSERVANCY at the London Headquarters, Belgrave Square, S.W.1—The Natural Environment Research Council, Establishments Division, State House, High Holborn, London, W.C.1 (January 7).

PROGRAMMER (with a degree or equivalent qualification, at least two years programming experience, and preferably a knowledge of Algol, Fortran or Elliott 803 machine code) in THE COMPUTING LABORATORY, to help in the provision of a computing service, by advising on the use of programmes and writing new programmes—The Registrar, University College of North Wales, Bangor, North Wales (January 7).

DEMONSTRATOR (graduate qualified in palaeontology, and preferably with at least an honours degree) in GEOLOGY at the University of Newcastle, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (January 8).

LECTURER or ASSISTANT LECTURER in THE PHILOSOPHY OF SCIENCE in St. Salvator's College—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (January 8).

LECTURER (with a distinguished academic record in mathematics, and preferably with interests in a branch of applied mathematics and some experience in computing) in MATHEMATICS at Wollongong University College, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 10).

WILLIAM JULIEN COURTAULD CHAIR OF HELMINTHOLOGY at the London School of Hygiene and Tropical Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 10).

LECTURER (Grade II) in METALLURGY within the DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar and Secretary, The University of Bristol, Bristol (January 12).

ASSISTANT LECTURER or LECTURER (preferably with qualifications in the philosophy of science) in the DEPARTMENT OF PHILOSOPHY—The Registrar, The University, Hull (January 14).

CHEMIST (with a degree or equivalent qualification) to assist in work on crop nutrition, especially with analysis of plants and soils from field experiments—Head, Broom's Barn Experimental Station, Higham, Bury St. Edmunds, Suffolk (January 14).

ASSISTANT LECTURER or LECTURER (registered member of the veterinary profession, preferably with previous experience in pathology) in VETERINARY PATHOLOGY, Royal (Dick) School of Veterinary Studies—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (January 15).

LECTURER in HYDROLOGY in the DEPARTMENT OF FORESTRY and NATURAL RESOURCES—The Secretary, The University, Edinburgh (January 15).

LECTURER or ASSISTANT LECTURER in BOTANY at the University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (January 15).

LECTURER (with a higher degree, and preferably previous university teaching experience) in GEOGRAPHY at the University of Newcastle, New South

Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 15).

ASSISTANT LECTURER or LECTURER (qualified to teach special aspects of either Russian or Latin American sociology in addition to other fields of sociology) in SOCIOLOGY—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (January 17).

CHAIR OF STATISTICS—The Secretary of the University Court, University of Glasgow, Glasgow (January 17).

LECTURERS in GEOLOGY, a LECTURER in BIOLOGY; a SENIOR LECTURER in CHEMISTRY, an ASSOCIATE PROFESSOR/SENIOR LECTURER in PSYCHOLOGY; a SENIOR LECTURER/LECTURER in PHILOSOPHY, a SENIOR LECTURER/LECTURER in PHYSICS; and a SENIOR LECTURER/LECTURER in MATHEMATICS at Macquarie University, Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar, Macquarie University, P.O. Box 458, North Sydney, Australia (January 17).

SENIOR LECTURER or READER in SOCIOLOGY, with special responsibility for mathematical sociology—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (January 17).

SENIOR LECTURER in the DEPARTMENT OF PATHOLOGY—The Registrar, The University, Sheffield (January 22).

LECTURER (with a superior academic record in mechanical, civil or electrical engineering) in ENGINEERING at the University of New South Wales, Broken Hill Division—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 24).

ASSISTANT LECTURER (with interests in genetics or cytology) in BOTANY—The Registrar, The University, Hull (January 25).

BIOCHEMIST (with M.Sc. or Ph.D. in biochemistry or physiological chemistry or equivalent, and at least three years experience of biochemistry or clinical pathology) for the Cork Health Authority—The Secretary, Local Appointments Commission, 45 Upper O'Connell Street, Dublin 1, Republic of Ireland (January 25).

RESEARCH ASSISTANT in the GEOGRAPHY of the MIDDLE EAST—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 28).

CHAIR of MATHEMATICAL STATISTICS—The Registrar, The University, Hull (January 28).

LECTURER in VETERINARY PHYSIOLOGY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 28).

PROFESSOR of the ARCHAEOLOGY of the ROMAN EMPIRE—The Registrar, University Registry, Oxford (January 29).

ASSISTANT LECTURER in the DEPARTMENT of ZOOLOGY (duties will include teaching in the field of vertebrate zoology)—The Secretary, University College, Gower Street, London, W.C.1 (January 31).

EMBRYOLOGIST (scientist with research experience in embryology or developmental genetics)—The Director, Poultry Research Centre A.R.C., West Mains Road, Edinburgh, 9 (January 31).

JAMES WATT CHAIR of MECHANICAL ENGINEERING—The Secretary of the University Court, The University, Glasgow (January 31).

LECTURER in NUCLEAR PHYSICS, and a LECTURER in THEORETICAL PHYSICS—The Secretary, The University of Lancaster, Bailrigg House, Lancaster (January 31).

LECTURER in PURE MATHEMATICS—The Secretary, The Queen's University, Belfast, Northern Ireland (January 31).

LECTURER (with a good honours degree in engineering or an equivalent qualification, and preferably some industrial experience) in the STRENGTH of MATERIALS SECTION of the DEPARTMENT of MECHANICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (January 31).

SENIOR LECTURER in MECHANICAL ENGINEERING—The Secretary, The Queen's University, Belfast Northern Ireland (January 31).

SENIOR LECTURER in METEOROLOGY in the DEPARTMENT of MATHEMATICS, Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, January 31).

CHAIR of GEOLOGY and MINERALOGY—Secretary to the College, Trinity College (University of Dublin), Dublin, Republic of Ireland (February 1).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS in VARIOUS BRANCHES of CHEMISTRY, including INORGANIC CHEMISTRY, CHEMICAL ENGINEERING, ENGINEERING, TECHNOLOGY, PHYSICS and ALLIED SUBJECTS—The Registrar, The University, Manchester, 13 (February 14).

TURNER and NEWALL RESEARCH FELLOWS in ENGINEERING, INORGANIC CHEMISTRY, PHYSICS and ALLIED SUBJECTS—The Registrar, The University, Manchester, 13 (February 14).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (preferably with the degree of Ph.D. or equivalent research experience) in APPLIED MATHEMATICS, BIOCHEMISTRY, ENGINEERING CHEMISTRY, PHARMACOLOGY; PHYSICS or CHEMICAL ENGINEERING—The Secretary, The University, Edinburgh (February 15).

CHAIR of PURE MATHEMATICS at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or The Registrar of the University (New Zealand and London, February 28).

LECTURER (with a degree in pure science or agricultural science) in ENTOMOLOGY at Lincoln College University of Canterbury, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, March 31).

POST-DOCTORAL RESEARCH FELLOW in TREE PHYSIOLOGY in the SCHOOL of FORESTRY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, March 31).

BIOCHEMIST (Basic Grade) to work with and assist the Senior Biochemist—The Secretary, City General Hospital, Stoke-on-Trent, Staffordshire

POSTGRADUATE RESEARCH ASSISTANT in the DEPARTMENT of BOTANY for work on British ashwoods—The Registrar, The University of Sheffield, Sheffield.

RESEARCH ASSISTANT (pharmacology, physiology or zoology graduate) for comparative work on the control of heat production in newborn and adult animals—Dr. R. E. Moore, Department of Physiology, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

RESEARCH ASSISTANT (preferably with a degree in agriculture, agricultural botany, botany or equivalent qualifications) in the POTATO BRANCH to assist in investigations into the effects of herbicides on varieties of potatoes—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

SCIENTIFIC INFORMATION OFFICER (with a degree in agriculture or related subjects and a flair for languages, including English) to join a team engaged in publishing the latest research findings on temperate and tropical grasslands

and annual field crops in two journals of international repute—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, near Maidenhead, Berks.

TECHNICAL OFFICER FOR HERBAGE SEED CROPS, and a TECHNICAL OFFICER FOR CEREAL SEED CROPS (candidates should have a sound basic training in agriculture and possess a recognized diploma)—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

University of Oxford. Lord Nuffield's Benefaction for the Advancement of Medicine—Report for 1963-64. Pp. 28. (Supplement No. 1 to the *University Gazette*, Vol. 96, October 1965.) 2s. 6d. Report of the Committee on the Disciplinary Powers of the Vice-Chancellor and Proctors. Pp. 9 (Supplement No. 2 to the *University Gazette*, Vol. 96, October 1965.) 2s. 6d. (Oxford: The University, 1965.) [311]

Water Resources Board. Estimating Frequencies Using Probability Paper. By R. B. W. Bannerman. Pp. 17. (T.N.4) (Reading: Water Resources Board, 1965.) [311]

Column, Vol. 1, No. 1 (Autumn 1965). Edited by D. Barnes (The W. G. Pye Journal of Gas Chromatography) Pp. 8. (Cambridge: W. G. Pye and Co. Ltd., 1965.) Gratic. [311]

Space, No. 2 (May 1965). Edited by Miles Henslow. Pp. 49-96. Subscription rate for 12 numbers: 40s.; 6 dollars. (London: Cockatrice Press, Ltd., 1965.) [311]

Ministry of Technology. Forest Products Research Laboratory Leaflet No. 47: The Movement of Tumbers. Pp. 7. (London: H.M. Stationery Office, 1965.) 9d. net. [311]

The World Land Use Survey. Occasional Papers No. 3: Land Use Statistics of the Countries of Europe. By Sir Dudley Stamp. Pp. vi+42. (Bude, Cornwall: Geographical Publications, Ltd., 1965.) 10s. [311]

Planning, Vol. 31, No. 491 (October 1965): Reforming the Commons. By Members of the Study of Parliament Group. Pp. 287-312. 6s. *Planning*, Vol. 31, No. 492 (November 1965) Public Patronage of the Arts. By John Higgins. Pp. 313-332. 5s. (London: Political and Economic Planning, 1965.) [311]

The Royal Society. Provisional United Kingdom Contribution to Phase-Of the International Biological Programme. Prepared by British National Committee for the International Biological Programme. Pp. 65. (London: The Royal Society, 1965.) [311]

Report of the Agricultural Research Council for the years 1963-65. (Cmd. 2792) Pp. vi+121. (London: H.M. Stationery Office, 1965.) 8s. net. [311]

University of Birmingham: Faculty of Science and Engineering. Postgraduate Prospectus 1966. Pp. 75+8 photographs. (Birmingham: University of Birmingham, 1965.) [311]

Bulletins of Marine Ecology, Vol. 6, Part 5 Continuous Plankton Records Atlantic and the North Sea. By Dr. J. M. Colebrook and G. A. Robinson. Continuous Plankton Records—Contribution Towards a Plankton Atlas of the North Atlantic and the North Sea. Part 10: *Navicula planamembranacea* Hendey. By G. A. Robinson. Pp. 123-145+plates 62-66. (Edinburgh: The Scottish Marine Biological Association, 1965.) 11s. 6d. [311]

University of Oxford. Oration by the Vice-Chancellor and Annual Report, 1964-1965. Pp. 37-56. (Supplement to *Oxford University Gazette*, No. 3249.) (Oxford: The University, 1965.) 2s. [311]

Building Research Station Digest (Second Series), No. 63. Soils and Foundations—I. Pp. 6. (London: H.M. Stationery Office, 1965.) 4d. [311]

Ministry of Housing and Local Government. River Wye Basin: Hydrological Survey (Hydrometric Area, No. 55). Pp. v+57. (London: H.M. Stationery Office, 1965.) 12s. 6d. net. [311]

Philosophical Transactions of the Royal Society of London. Series A: Mathematical and Physical Sciences. No. 1088, Vol. 258 (28 October 1965): A Symposium on Continental Drift. Organized for the Royal Society by Prof. P. M. S. Blackett, F.R.S., Sir Edward Bullard, F.R.S., and Prof. S. K. Runcorn, F.R.S. Pp. xi+1-323+A1-A6 140s.; 21 dollars. Series B: Biological Sciences. No. 759, Vol. 249 (7 October 1965): The Biological Report of the Royal Society Expedition to Tristan da Cunha, 1962. By D. B. Baird, J. H. Dickson, M. W. Holdgate, and N. M. Wace. Pp. 257-434+plates 32-47. 85s.; 12.75 dollars. No. 760, Vol. 249 (7 October 1965) Evidence for a Dual Control, by Neurosecretion, of Hormone Synthesis and Hormone Release in the Pituitary of the Dogfish *Scyliorhinus stellaris*. By Sir Francis Knowles. Pp. 435-456+plates 48-59. 26s.; 3.90 dollars. (London: The Royal Society, 1965.) [311]

New Materials and Processes in Instrument Manufacture. Edited by P. J. Geary. (Proceedings of the SIRA Conference, Eastbourne, England, 13-14 May 1965.) Pp. 108. (Chislehurst, Kent: British Scientific Instrument Research Association, 1965.) 80s.; 12 dollars. [311]

Royal Observatory Bulletin, No. 99: Studies of the Globular Cluster ω Centauri. II. Radial Velocities of Bright Members. By G. A. Harding. Pp. E65-E78+2 plates. (London: H.M. Stationery Office, 1965.) 3s. net. [311]

Report of the Medical Research Council, October 1963-March 1965. (Cmd. 2787) Pp. ix+326+4 plates. (London: H.M. Stationery Office, 1965.) 20s. net. [411]

General Register Office. The Registrar General's Quarterly Return for England and Wales—Births, Deaths and Marriages, Infectious Diseases, Weather; Population Estimates, Quarter ended 30th June 1965. (No. 466, 2nd Quarter 1965) Pp. 40. (London: H.M. Stationery Office, 1965.) 2s. 6d. net. [411]

Imperial College of Science and Technology (University of London). Propulsion Without Wheels. By Prof. E. R. Laithwaite (Inaugural Lecture, 16 February, 1965.) Pp. 95-107. (London: Imperial College of Science and Technology, 1965.) 5s. [411]

Other Countries

Commonwealth of Australia. Department of External Affairs. Australian National Antarctic Research Expeditions. ANARE Interim Reports. Series A (4): Glaciology. Publication No. 79: The Photoelectric Metering of Wind-Blown Snow. By I. H. Landon Smith and B. Woodberry. A New Photoelectric Drift Snow Gauge. By E. R. Wishart. Pp. 26. (Melbourne: Antarctic Division, Department of External Affairs, 1965.) [511]

Canada. Department of Mines and Technical Surveys. Geological Survey of Canada. Paper 64-39: Groundwater Hydrology and Water Supply in the District of Mackenzie, Yukon Territory, and Adjoining Parts of British

Columbia. By L. V. Brandon. Pp. vii+102 (3 plates). 75 cents. Paper 64-43: The Design of a Spinner-Type Remanent Magnetometer. By A. Laroche. Pp. v+25+plate 1. 35 cents. Paper 65-4: Geological Survey of Canada—Radiocarbon Dates IV. By W. Dyck, J. G. Fyles and W. Blake Jr. Pp. 23. 35 cents. Paper 65-10: Rocks and Minerals for the Collector—Northeastern Nova Scotia, Cape Breton, and Prince Edward Island. By Ann P. Sabina. Pp. vii+76 (6 plates). 75 cents. Paper 65-15: A Depositional Study of the Harbour Seam, Sydney Coalfield, Nova Scotia. By P. A. Hachebard, A. R. Cameron and J. R. Donaldson. Pp. iv+81. 75 cents. Paper 65-16: Structural Analysis of Three Extension Faults Number 4 Mine, Canmore, Alberta. By D. K. Norris. Pp. iii+11. 75 cents. Paper 65-18: Field and Laboratory Methods Used by the Geological Survey of Canada in Geochemical Surveys. No. 8. Preparation of Geological Materials for Chemical and Spectrographic Analysis. By P. J. Lavery. Pp. iv+23 (6 plates). 75 cents. (Ottawa: Queen's Printer, 1965.) [511]

Merentutkimuslaitoksen Julkaisu. Havforskningsinstituttet Skrift. No. 208 The Gulf of Bothnia in Winter Time. I. Data from Winter Cruises 1959-63. Pp. 91. No. 214 The Baltic Cruises with R/V *Aranda* 1961-Hydrographical Data. Pp. vii+68. (Helsinki: Merentutkimuslaitoksen Havforskningsinstituttet, 1965.) [511]

South Africa Council for Scientific and Industrial Research. C.S.I.R. Research Report No. 208: Principles of Mass Housing. (Based on a series of lectures on housing delivered to post-graduate students in Town and Regional Planning, 1962) Pp. xx+118. C.S.I.R. Research Report 207: Technical High Schools. Recommendations of the Vocational School Buildings Committee. Pp. viii+67. (Pretoria: Council for Scientific and Industrial Research, 1965.) [511]

World Meteorological Organization. Technical Note No. 68: Meteorological Aspects of Atmospheric Radioactivity. (Papers presented by WMO experts during the 13th Session of the United Nations Scientific Committee on the Effects of Atomic Radiation) Pp. 194. (WMO-No. 169 TP.83) (Geneva: World Meteorological Organization, 1965.) 18 Sw. francs. [511]

Bibliography of Vitamin E, Vol. 6: 1960-1964. Compiled by Wilma F. Kujawski. Pp. 166. (Rochester, New York: Distillation Products Industries, 1965.) [511]

Australia. Commonwealth Scientific and Industrial Research Organization Soil Publication No. 22: Soil Development Associated with Stranded Beach Ridges in South-East South Australia. By G. Blackburn, R. D. Bond and A. R. P. Clarke. With an Appendix by N. H. Ludbrook. Pp. 66+4 maps. (Melbourne: Commonwealth Scientific and Industrial Research Organization, 1965.) [511]

South Australia. Institute of Medical and Veterinary Science. 26th Annual Report of the Council, July 1963-June 1964. Pp. 83. (Adelaide: Government Printer, 1965.) [511]

National Museum of Canada. Natural History Papers, No. 30 (August 18, 1965). New Restoration of Hadrosaurian Dinosaur. By C. M. Sternberg. Pp. 5. Anthropology Papers, No. 10: Preliminary Excavations at a Cobble Tool Site (D.R. 7) in the Fraser Canyon, British Columbia. By Donald H. Mitchell. Pp. 20+11 plates. (Ottawa: Queen's Printer, 1965.) [511]

Sandia Corporation. Fallout Report Beta-Gamma Radioactivity in Air at Sandia Laboratory. January through June 1965. By R. E. Womelsdoff. Pp. 12. (Albuquerque, New Mexico: Sandia Corporation, 1965. Available from the Clearinghouse for Federal Scientific and Technical Information National Bureau of Standards, U.S. Department of Commerce, Springfield, Virginia.) [511]

Institut Royal Météorologique de Belgique. Annuaire-Rayonnement Solaire, 1964. Pp. vi+60. Bulletin Mensuel—Observations Ionosphériques Août 1965. Pp. 26. (Bruxelles: Institut Royal Météorologique de Belgique, 1965.) [511]

United States Department of the Interior. Geological Survey. Geophysical Abstracts, No. 224 (September, 1965). By James W. Clarke, Dorothy B. Vitalano, Virginia S. Neuschel and others. Pp. iii+695-781. (Washington: D.C.: Government Printing Office, 1965.) 35 cents. [511]

United States Department of the Interior. Geological Survey Bulletin 1198-C Bryophytes Associated with Mineral Deposits and Solutions in Alaska. By Hansford T. Shacklette. Pp. iii+18. 15 cents. Bulletin 1201-B Quaternary Geology of the Mount Chamberlain Area, Brooks Range, Alaska. By G. W. Holmes and Charles R. Lewis. Pp. iv+32+plate 1. Professional Paper 399-A: Geology of Ishigaki-shima, Ryukyu-retto. By Helen L. Foster. Pp. vi+119+plates 1-4. Professional Paper 433-C Transport and Dispersion of Labelled Bed Material, North Loup River, Nebraska. By W. W. Sayre and D. W. Hubbell. Pp. vi+48. 45 cents. Professional Paper 450-B: Diabase Sheets of the Taylor Glacier Region, Victoria Land, Antarctica. By Warren Hamilton. Pp. iv+71+plate 1. Professional Paper 470: Geology and Tungsten Mineralization of the Bishop District, California. By Paul C. Bateman. Pp. vii+208+plates 1-11. Professional Paper 476-A: Geology and Uranium Deposits in the Cave Hills Area, Harding County, South Dakota. By G. N. Piripingos, W. A. Chisholm and R. C. Kerpfer. Pp. iv+64+plates 1-4. Professional Paper 492: Thermal Springs of the United States and Other Countries of the World—a Summary. By Gerald A. Waring. Pp. ix+383. 2.75 dollars. Professional Paper 504-A: Glacial Reconnaissance of Sequoia National Park, California. By F. E. Matthes. Pp. x+58+plates 1 and 2. Professional Paper 604-B Postglacial Drainage Evolution and Stream Geometry in the Ontonagon Area, Michigan. By John T. Hack. Pp. iii+40+plate 1. (Washington: D.C.: Government Printing Office, 1965.) [511]

United States Department of the Interior. Geological Survey. Professional Paper 604-C Geology and Petrogenesis of the Island Park Caldera of Rhyolite and Basalt, Eastern Idaho. By Warren Hamilton. Pp. iv+37+plate 1. Professional Paper 525-C Geological Survey Research 1965, Chapter C. Pp. v+219. 2 dollars. (Washington, D.C.: Government Printing Office, 1965.) [511]
